SUBJECT INDEX TO VOLUME 74

- ABDOMEN**, injuries of, Problems of surgery in total war, with special references to abdominal injuries, 375, Nonpenetrating trauma of, 419, Gunshot wounds of, 425, Arteriography of abdominal organs by aortic injection, preliminary report, 655
- Abdominal wall, New method of repair for indirect inguinal hernia considered in reference to parietal anatomy, 697
- Abortion, Use of female sex hormones in clinical practice, 490
- Abscess, Value of sulfathiazole in treatment of peritonitis and, of appendical origin, 368
- Adenocarcinoma, Factors influencing end results in carcinoma of ovary, report of series of 138 patients treated from 1910 to 1935, 928
- Adhesions, abdominal, Free omental graft, clinical and experimental study, 1046
- Adrenal gland, Adrenal cortical tumors, types of nonhormonal and hormonal tumors, 281
- Air volume, Significance of changes in subdivisions of lung volume in Trendelenburg position, 1061
- Allergy, Retrobulbar neuritis in relation to sinus disease, 594
- American College of Surgeons—
Address of retiring president American surgery in changing world, 273
- Cancer, Role of radiologist in, clinic, 552, Trends in, research, 561, Symposium on, 549, 552, 555, 561, Present status of, problem, ed 766
- Clinical Congress, Proceedings of 31st annual, 1941, Boston, 273-648, 1941 meeting, 642, Defense needs suggest timeliness of College program for graduate training in surgery, 643, Boston Committee on Arrangements, 647, technical exhibition 648
- Fractures, Symposium on, and other traumas, 425, 428, 514, 529, 541, 546, Oration on, and other traumas General surgeon's approach to problems presented by, and other traumas, 514
- Fundamental surgical problems, Forum on, American surgery in a changing world, 273, 319, 343, 353, 361, 368, 433, 439, 446, 449, 458, 463, 468, 475, 479, 483, 496, 499, 505, 509
- Graduate training in surgery, Defense needs suggest timeliness of College program for, 643
- Hospital standardization Twenty fourth annual, conference, 645
- Neurological surgery as related to eye and ear, Symposium on, 585
- Ophthalmic surgery, Symposium on principles of, 589, 598, 610
- Oration on surgery, Some lessons learned in great war, 370
- Salivary gland, Symposium on, 569, 604
- Surgery of heterophoria and heterotropia, Symposium on 565, 567, 577, 628
- American Medical Association Council on Medical Education, American surgery in changing world, 273, Need for trained personnel in Army department of physical therapy, ed 1160
- Amputation Interscapulothoracic for malignant tumors of upper extremity report of 31 consecutive cases, 161, Some lessons learned in great war, 370, of lower extremities in occlusive arterial diseases 10 year review 821
- Anesthetics, metrazol Studies of, 1000
- Anastomosis, ureterointestinal, Experimental study of, implantation, V Destiny of implanted ureter, 129, ureterointestinal, Implantation of ureters into rectosigmoid with study of postoperative course, 221, Gastrostomy—jejunal intubation, 239, esophagogastric, Resection for carcinoma of esophagus, ed 266
- Anatomy, parietal, New method of repair for indirect inguinal hernia considered in reference to parietal anatomy, 697, gynecological, Further studies in, and related clinical problems, 709
- Androgens, Adrenal cortical tumors, types of nonhormonal and hormonal tumors, 281
- Anesthesia, Caudal, its use in obstetrics, 63, spinal, Continuous—serial, fractional, controllable, intermittent—spinal, with observations on 1000 cases, 948, cyclopropane, ether, ethylene, intravenous, local, nitrous oxide, spinal, in cases of poor surgical risk, some suggestions for decreasing risk, 1011
- Anesthetics, combustible, Hazards of fire and explosion of, agents, II In presence of cautery, 259, III In presence of diathermy, 895
- Aneurysm, arteriovenous, Subacute streptococcus viridans septicemia cured by excision of infected traumatic, 974
- Angioma, Vascular tumors of bone, pathological and clinical study of 27 cases, 777
- Angiosarcoma, Clinical and pathological study of leiomyosarcoma, hemangioendothelioma or, and fibrosarcoma of stomach, 671
- Ankle, Suppurative joint disease and its relation to pyogenic osteomyelitis, review of end results of 67 involved joints in 57 patients, modern chemotherapeutics, 796
- Antigen, Rh, Erythroblastosis neonatorum, an obstetrical pathological study of 47 cases, 1
- Antisepsis Protection of operative field with impermeable adhesive skin coating, preliminary report, 499
- Aorta, Arteriography of abdominal organs by aortic injection, preliminary report, 655
- Appendicitis, Treatment of acute, at University of Minnesota Hospitals, 1112
- Appendix, Retrocecal, its diagnosis and surgical approach 180, Value of sulfathiazole in treatment of peritonitis and abscesses of appendical origin 368, noninflamed, Appendiceal obstruction in 968, Treatment of acute appendicitis at University of Minnesota Hospitals, 1112
- Arm, Interscapulothoracic amputation for malignant tumors of upper extremity report of 31 consecutive cases, 161
- Arteriography, of abdominal organs by aortic injection, preliminary report, 655
- Arteriosclerosis obliterans, Amputation of lower extremities in occlusive arterial diseases 10 year review 821
- Artery, gastroduodenal, pancreaticoduodenal, Excision of head of pancreas for carcinoma with studies of its blood supply 137, Management of acute embolic occlusion of to extremities 236, Arteriography of abdominal organs by aortic injection, preliminary report 655, Amputation of lower extremities in occlusive arterial diseases 10 year review 821
- Asepsis Human bites of hand 153, Treatment of burns 428, Nine years' clinical experience with steel wire as suture material 845, Treatment of patients with severe burns 914

- Asphyxia, experimental. Phenomenon of asphyxial resuscitation. I. Resuscitation with inert (asphyxiating) gas in advanced, 978
- Aspiration, Peritoneal, in diagnosis of strangulated bowel, 8
- Atropine, Study of effect of morphine, and atropine on bronchi, 851
- BACKACHE**, ed. 90
- Bacterial infection, staphylococcal, 4
- Bladder. Nonpenetrating trauma of abdomen, 4 p. Ectropism of scrotum in which normal, and urinary control have been obtained by plastic operations, 740. Scrofula and postoperative treatment of large calyceal and rectovaginal fistulas, 738
- Bile duct, hepatic, Functional disturbances of the cholodochus and, 306 Clinical significance of serum enzyme test in diagnosis of acute pancreatitis, 450 External biliary fistulas, study of, 1 cases, 834
- Bile flow. Study of mechanics of, I. Responses to physiological intravenous solutions, 27, II. Responses to intraduodenal solutions, 603 III. Responses to pharmacological stimuli, 96
- Biliary colic, Pneumonia as complication of 68
- Biliary tract, Obstruction. Jaundice, ed. 768
- Biopsy. Testicular. Further studies in male infertility. 836 decidua, Significance of bleeding in early pregnancy as evidenced by, 30
- Bites, Human, of hand, 53
- Bleeding. Significance of in early pregnancy evidenced by decidua biopsy, 30
- Blood, Clinical studies on antihemorrhagic effects of new water-soluble vitamin K-like substance 35 E. alteration of, and, substitutes, 345 Problems of surgery in total war. Its special references to abdominal injuries, 375; Effect of distention of small intestine, anoxemia and oxygen therapy upon flow of bile and urine in dog; relationship to hepatorenal syndrome 446
- Blood chemical change, Changing concepts of accepted treatment for acute hematogenous osteomyelitis, ed 5
- Blood plasma, Hypoproteinemia and liver function, 403
- Blood studies, Erythroblastosis neonatorum, obstetrical-pathological study of 47 cases, ; Multiple myeloma, 24
- Blood supply. Excision of head of pancreas for carcinoma with studies of its, 37
- Blood transfusions, Staphylococcus septicemia, observations relative to state of hydration in dog and in man, 333
- Blood tubes, Implantation of ureters into rectosigmoid with study of postoperative course 23
- Blood vessels, Vascular tumors of bone, pathological and clinical study of 37 cases, 777 Circulation in normal and arthritic clots, 8
- Blood volume, I. Effect of plasma transfusion upon serum proteins and, of dogs rendered hypoproteinemic by diet, 343
- Bone, Infection of. Changing concepts of accepted treatment for cut hematogenous osteomyelitis, ed. 5 sarcoma, Interosseous diaphyseal amputation for malignant tumors of upper extremity. report of 31 consecutive cases, 6 diseases of, Recurrent fracture, 304 Reaction of to metals, II. Lack of correlation. Its electrical potentials, 3 surgery of, Factors in choice of material for plates and screws, 54 Results in compound fractures. Its osteomyelitis as experienced by Veterans Administration over past 30 years, 346 tumors of, Vascular pathological and clinical study of 37 cases, 777
- Bone healing, Treatment of fresh traumatic and contaminated scrofula, 20
- Bone marrow. Multiple myeloma, 34
- Bowel, strangulated, Peritoneal aspiration in diagnosis of 37; Implantation of ureters into rectosigmoid. Its study of postoperative course, Injuries of, Problems of surgery in total war with special references to abdominal injuries, 375; Diagnosis and management of incarcerated and strangulated femoral hernia, 1005
- Brain, Visual field changes and subdural hematomas, 406 Helium in encephalography 760 Abscess, cyst, Contrast media in cysts and abscesses of cerebral hemisphere, 683
- Breast, M. urinary carcinoma, review of 3,636 cases, 75 Endocrine aspects of chronic mastitis, further report on rates of estrogen excretion and results of hormone therapy, 336 Cancer of, 10 year end-results, 763 Cancer of, "pale epithelium" in mammary gland and its experimental production in Rhesus monkey 906
- Bronchus, Study of effect of morphine, atropine, and atropine on, 85
- Burns, Treatment of 478 General surgeon approach to problems presented by fractures and other traumas, 514 Treatment of patients with severe, 9 4
- CANCER**, of stomach, Diagnosis and treatment of, 487 Procarcinoma lesions, 340 of breast, year end-results, 763 Present status of, problems, ed. 766 of cervix, Complications of radiotherapy in, 867 Modern management of of lower gastrointestinal tract, 003 of uterus, Removal of regional lymph nodes in, of body of, 003 of rectum, Extension of indications for radical operation in, ed. 025 of corpus uteri, Persistence of tumor after preoperative radium treatment for 06
- Cancer clinic, Role of radiologist in, 552
- Cancer research, Trends in, 95
- Carcinoma, of esophagus, Tork's operation, recovery 47; Mammary review of 3,636 cases, 75 of colon and rectum, study of metastasis and recurrences, 83 Excision of head of pancreas for. Its studies of its blood supply 37; Aseptic resection of stomach for and ulcer 36 Resection for of esophagus, ed. 366 Nature of virus associated with, in rabbits, 309 Radical surgical treatment for of cardiac end of stomach, 555; of ovary. Factors influencing end-results in, report of series of 38 patients treated from 1910 to 1915. 978 Field-free and invasive basal cell, basal-epithelioma type 28
- Cartilage. Spontaneous adolescence—Stratford-Maine disease, practical and theoretical considerations, 663
- Cataract, Management of ophthalmological surgical complications, 506
- Catgut sutures, Superiority of fine catgut over fine silk as suture in gastric surgery 640
- Caudal block, Caudal anesthesia, its use in obstetrics, 63
- Cautery. Hazards of fire and explosion of anesthetic agents, II. In the presence of, 39
- Cervix, Artificial decolour with 9 Volvulus of anatomical factors in its etiology, report of, 83; Modern management of cancer of lower gastrointestinal tract, 004
- Cerebellum, Basilar invagination of skull—so called platybasia, report of 3 cases in which operation was done 751
- Cerebrospinal fluid, Treatment of obstructive hydrocephalus in adults, 90
- Cerebrum, Otological symptoms or complications of craniocerebral injury 34 Contrast media in cysts and abscesses of cerebral hemisphere, 683

- Cheek, Principles of plastic surgery in treatment of malignant tumors of face, 449
- Chemistry, Ureteral stone, Stone in ureter, clinical data based on 500 cases, 1065
- Chemotherapy, and roentgen radiation in Clostridium welchii infections, clinical and experimental studies, 361, Suppurative joint disease and its relation to pyogenic osteomyelitis, review of end results of 67 involved joints in 57 patients, modern chemotherapeutics, 796
- Children, Recurrent fracture, 204
- Cholangiograms, External biliary fistulas, study of 23 cases, 828
- Cholecystitis, Acute, with perforation, ed 127
- Cholelithiasis, Functional disturbances of, and hepatic bile ducts, 306
- Circulation, venous, Significance of, about elbow in pathomechanics of Volkmann's contracture, 871, in normal and varicose veins, 1118
- Circulatory system, Subacute streptococcus viridans septicaemia cured by excision of infected traumatic arteriovenous aneurysm, 974
- Clavicle, Interscapulothoracic amputation for malignant tumors of upper extremity, report of 31 consecutive cases, 161
- Clostridium welchii infection, Chemotherapy and roentgen radiation in, clinical and experimental studies, 361
- Colectomy, Chronic idiopathic ulcerative colitis, report of 7 operated cases, 1087
- Colitis, Chronic idiopathic ulcerative colitis, report of 7 operated cases, 1087
- Colon, Carcinoma of, and rectum, study of metastasis and recurrences, 83, Artificial ileocecal valve, 92, Supplementary and synergistic action of stimulating drugs on motility of human, 809, Volvulus of cecum, anatomical factors in its etiology, report of case, 882, Modern management of cancer of lower gastrointestinal tract, 905, Chronic idiopathic ulcerative colitis, report of 7 operated cases, 1087
- Combustion hazards of anesthetics, Hazards of fire and explosion of anesthetic agents, II In presence of cautery, 259, in presence of diathermy, 895
- Contracture, Volkmann's, Significance of venous circulation about elbow in pathomechanics of, 871
- Contrast medium, colloidal thorium dioxide, Contrast media in cysts and abscesses of cerebral hemisphere, 983
- Coramine, Studies of anaesthetics II Metrazol, 1020
- Cranium, Treatment of obstructive hydrocephalus in adults, 99, Otological symptoms or complications of craniocerebral injury, 581, Intracranial infections and their spread from ear and nasal accessory sinuses, 585, Basilar invagination of skull—so called platybasia, report of 3 cases in which operation was done, 751
- D**EBILITATED patient, Gastrostomy—jejunal intubation, 239
- Defense, needs suggest timeliness of College program for graduate training in surgery, 643
- Diabetes, Amputation of lower extremities in occlusive arterial diseases, 10 year review, 821, Anesthesia in cases of poor surgical risk, some suggestions for decreasing risk, 1011
- Diagnosis, Importance of complete, to successful treatment of strabismus, 565
- Diaphragm, Anatomy and surgery of diaphragmatic hernia, ed 1026
- Diathermy, surgical, Hazards of fire and explosion of anesthetic agents, III In presence of diathermy, 895
- Diet, protein free, I Effect of plasma transfusion upon serum proteins and blood volume of dogs rendered hypoproteinemic by, 343, Biological test proposed as guide in administration of thiamin, 1154
- Diethylstilbestrol, Studies in, II Differences in response of radium induced and physiological menopause III Effect on liver, 686
- Dislocation, of shoulder joint, Extra articular operation for recurrent, 755
- Disease, Struempell-Marie, Spondylitis adolescens, practical and theoretical considerations, 663, occlusive arterial, Amputation of lower extremities in, 10 year review, 821
- Dressing, of wound, Treatment of patients with severe burns, 914
- Drugs, adrenergic, cholinergic, codeine, secretin-cholecystokinin, Study of mechanics of bile flow, III Responses to pharmacological stimuli, 961
- Duodenum, Study of mechanics of bile flow, I Responses to physiological intravenous solutions, 27, Excision of head of pancreas for carcinoma with studies of its blood supply, 137, Study of mechanics of bile flow, II Responses to intraduodenal solutions, 692, III Responses to pharmacological stimuli, 961, Role of hypertension and pancreatic erosion in massive fatal hemorrhage from gastric and duodenal ulcers, 1058
- E**AR, middle, Sulfonamide drugs in treatment of acute suppurations in, and mastoid, 573, Otological symptoms or complications of craniocerebral injury, 581, Intracranial infections and their spread from, and nasal accessory sinuses, 585
- Edema, of pancreas, 123
- Education, in anesthetics, Hazards of fire and explosion of anesthetic agents, II In presence of cautery, 259, III In presence of diathermy, 895, Present status of cancer problem, ed 766
- Elbow, Suppurative joint disease and its relation to pyogenic osteomyelitis, review of end-results of 67 involved joints in 57 patients, modern chemotherapeutics, 796, Significance of venous circulation about, in pathomechanics of Volkmann's contracture, 871
- Electrical potentials, Reaction of bone to metals, II Lack of correlation with electrical potentials, 231
- Embolism, Management of acute embolic occlusion of arteries to extremities, 236
- Empyema, Putrid, 69
- Encephalography, Helium in, 760, Contrast media in cysts and abscesses of cerebral hemisphere, 983
- Endocrine therapy, Endocrine aspects of chronic mastitis, further report on rates of estrogen excretion and results of hormone therapy, 326
- Epithelium, Pale, in mammary gland and its experimental production in Rhesus monkey, 1098
- Ergotamine, Supplementary and synergistic action of stimulating drugs on motility of human colon, 809
- Erythroblastosis neonatorum, obstetrical pathological study of 47 cases, 1
- Erythrocytes, Erythroblastosis neonatorum, obstetrical-pathological study of 47 cases, 1

ERYTHROBLASTOSIS NEONATORUM

An Obstetrical-Pathological Study of 47 Cases

CARL T JAVERT, M D, New York, New York

ERYTHROBLASTOSIS neonatorum, or fetalis, has become a term used in the current literature when referring to hydrops fetalis, icterus gravis, and congenital anemia of the newborn, although Appleberg-Ulfspärre, Arnold and Downey, prefer the original terminology. These diseases of the fetus have in common a varying degree of erythroblastemia and erythroblastosis which is most marked in the hydrops variety. When immature white cells are numerous, the term erythroleucoblastosis is sometimes used, and in the earlier reports of both Jakesch and Klebs in 1878, and of Sanger in 1888, the condition was called fetal leucemia.

Hydrops fetalis has been recognized for centuries according to Ballantyne, who in 1898 collected 70 cases from the literature since 1614. The hematological picture was added by Schridde in 1910, and Rautman named the disease erythroblastosis in 1912. Icterus of the newborn has also been observed for centuries, but it remained for Blomfield in 1901 to differentiate physiological jaundice from icterus gravis. Even as late as 1908 Pfannenstiel held that icterus gravis was an intensification of physiological jaundice. The familial nature

of icterus gravis was noted by Buchan and Comrie, and they also called attention to the large numbers of nucleated red cells in the circulating blood as well as to the hematopoiesis in the liver and spleen. Ultimately, icterus gravis was included in the syndrome of erythroblastosis, and the subsequent reports of von Gierke, Yllpo, de Lange and Arntzenius, and others have substantiated this relationship. Although anemia is seen secondary to or associated with hydrops and icterus, congenital anemia *per se* was correlated with erythroblastosis neonatorum by Ecklin in 1919, with confirmatory reports by Susstrunk, Abt, and others. However, Hellman and Hertig regard the anemia only as a secondary manifestation of icterus gravis, to this we take exception, because of our own experience with 3 cases, as well as the reports in the literature. The occurrence of anemia and hydrops in infants of the same family as reported by Passachoff and Wilson, and anemia and icterus as reported by Diamond, Blackfan and Baty, may be regarded as further evidence that anemia is a separate entity.

It is often difficult to classify a given case of erythroblastosis fetalis into the hydropic, icteric, or anemic types because of the overlapping of symptoms. However, the prominent clinical feature is selected when designating

livered infants with universal edema. The average parity was 3 2 and 3 1 for the two groups in contrast to 5 2 and 3 in the series of Hellman and Hertig.

Duration of gestation The average was 36 3 weeks for the hydrops group and 39 weeks for the icterus group, showing that the former were born 1 month or more prematurely. In Capon's series of hydrops cases, the average duration was 33 weeks.

Complications of pregnancy Capon, Hellman and Hertig, Darrow, and others state that the mother shows no characteristic pathognomonic signs. This may be true, but developments do occur during pregnancy and labor that should arouse suspicion, especially in the hydrops form of erythroblastosis, and include excessive uterine enlargement ("hydramnios") in 50 per cent, and toxemia of pregnancy in 31 per cent of the hydrops cases. Premature separation of the placenta, jaundice, and diabetes were present in several mothers.

Uterine enlargement out of proportion to the duration of pregnancy was frequently diagnosed as "hydramnios" clinically, and it has been so designated in the literature. The excessive uterine enlargement was found to be due to the combined weight of the placenta and infant, which in the hydrops cases averaged 4,674 grams, or 10 2 pounds. This is considerable for an average period of gestation of only 36 weeks. Figure 1 shows the placenta and infant of Case 1 which together weighed 4,950 grams, 10 7 pounds, the period of gestation was only 33 weeks. The edema of the infants makes them weigh more, so that they may be regarded as mature on the basis of weight when actually they are premature.

The incidence of toxemia of pregnancy was increased in both types of erythroblastosis, but was highest in the hydrops cases. Schumann found that 62 per cent of the cases reviewed by him had albuminuria and edema. Others, including de Lange, and Hellman and Hertig, found a high incidence of toxemia. Williamson and Vecchi have each reported a case of hydrops associated with postpartum eclampsia, and because of the rarity of such reports we record our own at this time.

CASE 1 Mrs S H, aged 27 years, Irish, parity 2-0-1-1,¹ who was delivered 3 years previously of an infant which died of icterus gravis. The Wassermann reaction was negative. The present pregnancy was complicated by an excessive weight gain of 25 kilograms, 55 pounds, by the thirty-second week of gestation. At this time an oliguria developed with

Fig 1 Case 1 Macerated fetus with hydrops type of erythroblastosis, weight, 2,750 grams at 33 weeks' gestation, weight of placenta, 2,200 grams. From Stander, H J *Williams Obstetrics*, 8th ed., 1941.

3 plus albumin in the urine, the blood pressure rising to 165/110 and remaining at that level. She received the routine treatment for pre-eclampsia, including intravenous glucose. The nonprotein nitrogen rose from 29 2 milligrams per 100 cubic centimeters to 50 8, the uric acid from 5 6 milligrams to 7 6 milligrams, the carbon dioxide combining power decreased from 32 9 to 27 7 volumes per cent. Polyhydramnios was suspected clinically because of the excessive uterine enlargement. Roentgenographic studies were, therefore, conducted in order to determine the presence of soft tissue edema or abnormality of the fetus, since erythroblastosis was suspected. No halo or corona was seen about the fetal head, but, within the uterus, the infant had a Buddha like habitus caused by the enlarged abdomen (Fig 1ob).

An induction of labor using castor oil, quinine, and an enema was successful, and, during the first stage of labor, the fetal heart was lost. The patient was delivered by breech extraction after a 7 hour labor. There was a postpartum hemorrhage of 700 cubic centimeters, which was attributed in part to the large placenta weighing 2,200 grams. It and the infant, which weighed 2,750 grams, had a combined weight of 4,950 grams, 10 2 pounds. Both are shown in Figure 1. The infant should have weighed about 1,600 grams for this period of gestation. Because of the postpartum hemorrhage, a blood transfusion was given to the mother. Three hours after delivery the mother developed two convulsive seizures. At this time she was given oxygen and molar lactate solution. Sixteen hours later, the nonprotein nitrogen had risen to 85 4 and the uric acid on the third postpartum day was 12 3 milligrams. Kidney function tests postpartum revealed a urea clearance of 73 5 per cent in 2 hours.

¹The patient has had 2 full term, 0 premature deliveries, 1 abortion and has 1 living child. Same explanation holds for Cases 3-6.

erythroblastosis as to type. During the course of this study we have observed 3 cases which had hemorrhagic diathesis as the first outstanding clinical sign. Such association is illustrated by Case 3. There were 3 other infants in our study that had erythroblastosis and erythroblastemia without clinical hydrops, icterus, anemia, or hemorrhagic diathesis. They probably died before any of these complications had time to develop since 2 died before delivery. Two of these cases were proved by autopsy while the third was too badly macerated for histological interpretation, but the cord blood was sufficiently well preserved to give the diagnosis. References were also obtained in the literature to reports of erythroblastosis without hydrops, icterus, or anemia by Salomonsen de Lange and Ferguson.

A classification of erythroblastosis neonatorum based on our experience with 47 cases and substantiated by reports in the literature is presented: erythroblastosis with hydrops, 16 cases; erythroblastosis with icterus, 22 cases; erythroblastosis with anemia, 3 cases; erythroblastosis with hemorrhagic diathesis, 3 cases; erythroblastosis without hydrops, icterus, anemia, or hemorrhagic diathesis (*unclassified*) 3 cases.

Such a classification has academic value in clarifying our knowledge of the disease. It also has practical value since the infant mortality rate varies with the different types of the disease, as will be shown subsequently.

INCIDENCE

The incidence of erythroblastosis varies according to the type of the disease. The hydrops infants have an incidence of 348 in our material, and 3800 in the series of Wolf and Neigus. The icterus form in our series was 286 as compared to 500 found by Hellman and Hertig. This wide range is presumably due to a failure to recognize and diagnose the cases as has been our experience in the years 1933 to 1935.

We observed only 7 cases in 1934, 9 premature and full term deliveries, or 1.545. During the period 1936 to 1940, we have had 40 cases in 7520 deliveries, or .533, an increase of nearly 400 per cent during the period of the present study.

Erythroblastosis is not frequently encountered yet one must be acquainted with it for

A 4th case of the milder form of erythroblastosis has been observed recently born to mother who had previous infants with icterus gravis.

definite reasons. The incidence is 100 per cent for the mother that bears one of these infants, particularly when the baby dies, as so many of them do. Erythroblastosis is responsible for 3.2 per cent of our fetal deaths. The doctor-patient relationship may become strained if an infant with erythroblastosis is delivered by cesarean section as in cases reported by A. F. Abt (Smyth's case), Bonney and Morton, and Pallas. A knowledge of this disease is necessary in making a differential diagnosis of other diseases of the newborn. It is noted that the medical examiners of the New York State Board asked a question on erythroblastosis in the examination on obstetrics in 1938. Finally, a research physician need feel no chagrin if his efforts bring knowledge and understanding of a disease even though much cannot be done from the standpoint of prevention and treatment. Prophylactic antepartum therapy for the child, for which Ballantyne first raised a plea, may be shown to have a practical application in erythroblastosis as it has in syphilis, and to that end, this study is dedicated.

MATERNAL DATA

Most of the following data have been obtained from 16 mothers bearing infants with hydrops, and 22 with icterus gravis. Inclusion of anemic, hemorrhagic, and unclassified types would be somewhat controversial and their number is too small anyway to be statistically important so they have not been tabulated except when stated.

Age. The average maternal age was 33 and 30 years for the hydrops and icterus groups respectively. Hellman and Hertig have recorded similar ages for the two groups.

Race. It is generally believed that erythroblastosis is seen more frequently in patients having Mediterranean ancestry while Ott reports a high incidence in the Scandinavian race.

In our material nearly all of the races attending clinic are represented. However, proportion to the line population, 30 per cent were Irish in contrast to 4.5 per cent for the clinic and 1 per cent are negroes, versus 6.6 per cent for the clinic showing higher incidence in the Irish and negro race.

Parity. In the total group of 47 mothers, there were only 3 primiparas, making multiparity decided factor 9 per cent of the patients. Potter reports 38 cases all in multiparas, and many others state that the first born escapes the disease. Schumann found 5 primiparas in 30 mothers that de-

livered infants with universal edema. The average parity was 3 2 and 3 1 for the two groups in contrast to 5 2 and 3 in the series of Hellman and Hertig.

Duration of gestation The average was 36 3 weeks for the hydrops group and 39 weeks for the icterus group, showing that the former were born 1 month or more prematurely. In Capon's series of hydrops cases, the average duration was 33 weeks.

Complications of pregnancy Capon, Hellman and Hertig, Darrow, and others state that the mother shows no characteristic pathognomonic signs. This may be true, but developments do occur during pregnancy and labor that should arouse suspicion, especially in the hydrops form of erythroblastosis, and include excessive uterine enlargement ("hydramnios") in 50 per cent, and toxemia of pregnancy in 31 per cent of the hydrops cases. Premature separation of the placenta, jaundice, and diabetes were present in several mothers.

Uterine enlargement out of proportion to the duration of pregnancy was frequently diagnosed as "hydramnios" clinically, and it has been so designated in the literature. The excessive uterine enlargement was found to be due to the combined weight of the placenta and infant, which in the hydrops cases averaged 4,674 grams, or 10 2 pounds. This is considerable for an average period of gestation of only 36 weeks. Figure 1 shows the placenta and infant of Case 1 which together weighed 4,950 grams, 10 7 pounds, the period of gestation was only 33 weeks. The edema of the infants makes them weigh more, so that they may be regarded as mature on the basis of weight when actually they are premature.

The incidence of toxemia of pregnancy was increased in both types of erythroblastosis, but was highest in the hydrops cases. Schumann found that 62 per cent of the cases reviewed by him had albuminuria and edema. Others, including de Lange, and Hellman and Hertig, found a high incidence of toxemia. Williamson and Vecchi have each reported a case of hydrops associated with postpartum eclampsia, and because of the rarity of such reports we record our own at this time.

3 plus albumin in the urine, the blood pressure rising to 165/110 and remaining at that level She received the routine treatment for pre eclampsia, including intravenous glucose The nonprotein nitrogen rose from 29 2 milligrams per 100 cubic centimeters to 50 8, the uric acid from 5 6 milligrams to 7 6 milligrams, the carbon dioxide combining power decreased from 32 9 to 27 7 volumes per cent Polyhydramnios was suspected clinically because of the excessive uterine enlargement Roentgenographic studies were, therefore, conducted in order to determine the presence of soft tissue edema or abnormality of the fetus, since erythroblastosis was suspected No halo or corona was seen about the fetal head, but, within the uterus, the infant had a Buddha-like habitus caused by the enlarged abdomen (Fig 10b)

An induction of labor using castor oil, quinine, and an enema was successful, and, during the first stage of labor, the fetal heart was lost The patient was delivered by breech extraction after a 7 hour labor There was a postpartum hemorrhage of 700 cubic centimeters, which was attributed in part to the large placenta weighing 2,200 grams It and the infant, which weighed 2,750 grams, had a combined weight of 4,950 grams, 10 2 pounds Both are shown in Figure 1 The infant should have weighed about 1,600 grams for this period of gestation Because of the postpartum hemorrhage, a blood transfusion was given to the mother Three hours after delivery the mother developed two convulsive seizures At this time she was given oxygen and molar lactate solution Sixteen hours later, the nonprotein nitrogen had risen to 85 4 and the uric acid on the third postpartum day was 12 3 milligrams Kidney function tests postpartum revealed a urea clearance of 73 5 per cent in 2 hours

The first maternal prothrombin determination as done immediately postpartum. It was 68 per cent of normal, and on the following day it was 61 per cent. Thyloquinone was given (10 mgm) intramuscularly and on the third postpartum day the prothrombin was still 61 per cent, indicating probable failure of the liver to utilize the thyloquinone because of damage. This patient has been followed 18 intervals in the past 6 months and the prothrombin level is still considerably lower than normal. Further evidence of liver damage may be obtained from a study of the serum proteins during pregnancy for levels as low as 3.4 grams per 100 cubic centimeters were found.

Examination of the cord blood revealed 458 normoblasts and 87 erythroblasts per 100 white cells. The total white count was 50,000 of which 30,700 were nucleated red cells. The mean red cell diameter was 0. μ . There were many immature white cells in the smear. The hemoglobin was 12 per cent (gm Sahli) red blood corpuscles, 500,000 color index, 1.3 volume index, .5. The prothrombin and fibrinogen concentration of the cord blood were too low for determination—fetal death several hours previous. The serum proteins were also very low .9 grams per 100 cubic centimeters.

A autopsy revealed the characteristic pathology of the hydrops type of erythroblastosis. The liver was examined with interest because of the hydrops as well as the toxemia in the mother and it showed marked degeneration of the liver cords with associated postmortem changes.

Amniotic fluid. The color of the amniotic fluid has been described by many authors and the consensus is that it usually has golden yellow color. In some of our cases, the color was often obscured by the passage of meconium resulting from fetal distress, which is frequently seen in erythroblastosis. A golden yellow amniotic fluid observed when the membranes rupture prematurely should arouse suspicion (See Case 6.)

Fetal distress within the uterus. Auscultation of the fetal heart often revealed fetal distress which is indicative of intrauterine asphyxia. Sometimes the fetal heart as lost before the onset of or during labor. All the hydrops infants born alive and 50 per cent of the icterus infants required resuscitation by means of carbon-dioxide-oxygen mixture or the use of the Flagg apparatus. The fetal distress and asphyctic bruit were often helpful signs in making a correct antepartum diagnosis. The former also provided the indication for a large number of operative deliveries.

Operative incidence. In the hydrops group the operative incidence was 50 per cent, and it was 3 per cent in the icterus group (clinic per cent). Two mothers were delivered by cesarean section. One was performed for premature separation of the placenta and the other because of 3 previous sections. Chief indication for operative interference (forceps) was fetal distress which occurred in 56 per cent.

Blood loss in the third stage of labor. The average blood loss in the hydrops group was 461 cubic centimeters which is greater than the average of 271 cubic centimeters for the clinic while the amount in the icterus group was not increased, namely 233 cubic centimeters. The increase in the hydrops group was caused by postpartum hemorrhage which occurred in 5 cases or 31 per cent, whereas only 1 case with icterus had a hemorrhage. The excessive bleeding in the hydrops group was caused by atony due to the overdistended uterus, large size of the placenta with an increased uterine surface to bleed, friability of the cotyledons with retained portions requiring manual removal as in one case and the factors associated with operative delivery.

Placenta. The average weight in the hydrops group was 531 grams, the largest weighed 1,000 grams (Fig. 1). The average weight of the infants was 3,490 grams, giving an infant-placenta ratio of 3—normal 6:1. The average weight in the icterus cases was 693 grams, the largest weighed 1,000 grams. The average weight of the infants in this group was 3,441 grams so that the normal ratio of 6:1 was obtained.

Inspection of the placentas of the infants with hydrops invariably revealed a pale maternal surface deeply fissured forming cotyledons which were friable. The fetal surface and membranes were stained yellow in 6 of our cases. In others, it was gray and glistening. On standing the placenta basin filled rapidly with a yellow colored serum so that in a short time the placenta lost as much as 500 grams in weight. The large size of the placenta is thought to be a response on the part of the fetal organism to faulty metabolism requiring an increase in the placental surface. The placenta of the icterus infants was of normal size as a rule, there was little or no edema, the maternal surface had a normal red color with normal cotyledons, the fetal membranes were discolored in 4 cases.

Previous to the present study begun in 1936 only 1 placenta had been saved for examination which has been the experience of most writers. However in the past 5 years we have examined 26 placentas, which will be reported elsewhere in greater detail. Suffice it to state for the present that the placentas of the hydrops cases bear a close resemblance to syphilis so that an erroneous diagnosis may be made. There is abnormal basophilia, the villi are large and edematous with signs of immaturity as indicated by focal persistence of the Langhans layer and the presence of Hof-

Fig 2 Photomicrographs of placentas in erythroblastosis Low power a, left, Hydrops case Note large, edematous, immature villi and fetal vessel filled with nucleated erythrocytes b, Icterus case Villi are more mature although some have edema Fetal vessel has fewer nucleated red cells

bauer cells (Fig 2a) The amnion and chorion often exhibit cells laden with a brownish pigment similar to that seen in the fetal liver and other organs The first histological report of the placenta was made by Goormaghtigh in 1927 He observed foci of hematopoiesis as have Hellman and Hertig We regard the immature red cells, erythroblasts and normoblasts in the fetal vessels of the placenta as of greater diagnostic value

The placentas of the icteric infants showed more mature villi although some showed slight edema The fetal vessels contained fewer normoblasts and occasional erythroblasts Basophilia was also less marked (Fig 2b)

Family history This term is a misnomer A better designation would be "obstetrical history," or "maternal history," since the mother gives a history of bearing infants with the disease Her family history as well as that of the husband fails to reveal a similar tendency Erythroblastosis in repeated pregnancies has been reported by de Lange and many others

Erythroblastosis usually appears in the second or third, or even the fifth pregnancy, as a rule, although

primiparas may have infants with the disease When the first born has had erythroblastosis, it is very likely to recur in subsequent infants In the literature, Buhrman and Sanford, Commandeur, Diamond et al, Fleischmann and Wolff, Jatho, Zimmermann and Yannett, each report erythroblastosis in the first pregnancy with repetition in successive pregnancies Their cases together with 3 of our own have had a total of 27 pregnancies resulting in only 1 healthy infant without erythroblastosis

The occurrence of erythroblastosis in terms of total number of pregnancies was 34.2 per cent for the hydrops group, and 31.4 per cent in the icterus group These percentages are in close agreement with those of Macklin, 30 and 58 per cent, respectively The hydrops group had more abortions than the icterus group, as well as history of erythroblastosis in previous infants These mothers have no difficulty in becoming pregnant, which speaks for the normalcy of the ova and sperm

There were 131 pregnancies in the hydrops and icterus groups resulting in 43 infants with erythroblastosis These were studied as to the appearance of erythroblastosis, and it was found that the lowest incidence occurred in the first pregnancy and that the tendency increased with successive pregnancies The percentages were approximately the same for both the hydrops and icterus groups Recurrence of erythroblastosis after its first appearance is about 50 per cent for the hydrops group and 40 per cent

Fig. 3. Infants with hydrops type of erythroblastosis. a, left, Case 3. Child weighed 3,070 grams at 37 weeks gestation; placenta weighed 600 grams. Pronounced anhydria found as separated from chest and abdomen as an aid to resuscitation. Death occurred 5 minutes after delivery. b, Dissection to show enlarged heart, liver, and spleen. (From Wolfe, S. A., and Nelson, I. *Am. J. Obst.*)

for the icterus group. Hellman and Hertig report 50 and 80 per cent for the two groups respectively.

The delivery of normal infants after the appearance of erythroblastosis in the previous infant was observed in 4 patients (not primiparas). These infants had no special prenatal therapy nor was there a change in husbands. However these mothers had had normal infants prior to the appearance of erythroblastosis.

Multiple pregnancy. Erythroblastosis has been reported in twins by Woolley, Oberdorfer, MacMillan, Abt, Buhrman and Sanford, and Andrews and Miller. Veterinarians have observed the hydrops form in one of litter of pups. Sometimes one twin is normal, as in de Lange's case. MacMillan found in her survey of the literature that when one twin had hydrops, the other was normal in 8 out of 9 cases, whereas with icterus, both twins were so affected in 5 out of 7 cases. Unfortunately most of the reports fail to distinguish between identical or fraternal twins. This is of importance since erythroblastosis may be congenital disturbance affecting only one twin, as in MacMillan's case of identical twins, whereas both of the monozygotic twins reported by Snyder and Ford had fetal hydrops.

Of our 47 cases, only one mother had single ovum twins (female), one of which was dead-born and macerated and had the unclassified type of erythroblastosis; the other died at the age of 2 days of congenital anemia, prematurity and cardiac hypertrophy. Other features of this case are as follows:

CASE. Mrs. E. T. Hungarian, 26 years old, primigravida. She had a successful pregnancy; the diagnosis of twins having been confirmed by x-ray. The Wassermann was negative. Labor began spontaneously in the thirty-eighth week of gestation, and after 9 hour labor in A, weighing 30 grams, as delivered by breech extraction. It lived for 3 days and developed petechiae and convulsions. Examination of the cord blood at birth revealed a red corpuscle count of 3,500,000, hemoglobin 5 grams, the white cell count, 55,000 and 20 erythroblasts and 95 normoblasts per 100 white cells. The cord prothrombin was 7 per cent of normal, the fibrinogen was 25 grams per cent (without evidence of hemorrhagic diathesis). During life transfusions were given and 2 milligrams of synthetic vitamin K (thylquinone Squibb). The infant died on the second day of life. The prime pathological features comprised large heart, eight to 30 grams, hematopoiesis of the liver and spleen, thick areas of focal necrosis in the former.

Twin B was a deadborn and macerated female weighing .050 grams. A smear of cord blood showed 6 erythroblasts and 7 normoblasts per 100 white cells. The white cell count was 3,000. Since the blood was hemolyzed, no further studies were made. Autopsy revealed marked a tolysis so that histological diagnosis could not be carried out. The placenta weighed 800 grams and examination of the membranes confirmed the diagnosis of single ovum twins. Grossly the placenta revealed deeply stained membranes for twin B and histologically the outstanding criteria were the normoblasts in the fetal vessels.

The diagnosis of erythroblastosis of the unclassified type was made on twin B while twin A was considered as having the anemic form of the disease. It is probable that had twin B been born alive it might have developed anemia or icterus and could then have been classified in the conventional manner.

Blood studies. Fifteen mothers (7 hydrops) had complete hematological examination including smear while the rest had a average of two or more hemoglobin determinations during the puerperium course. All were (than normal limits, save for mild anemia) cases. Moore and Pastore have reported a case of erythroblastic splenomegaly in a mother who delivered a normal infant. Doe reports the occurrence of erythroblastosis in the blood of

Fig. 3. Infants with hydrops type of erythroblastosis. a, left, Case 5. Child weighed 3,070 grams at 37 weeks' gestation; placenta weighed 600 grams. Pronounced asphyxia. Fluid was aspirated from chest and abdomen as an aid to resuscitation. Death occurred 5 minutes after delivery. b, Dissection to show enlarged heart, liver and spleen. (From Wolfe, S. A. and Neiger, L. *Am. J. Obst.*)

for the icterus group. H. H. Homan and Hertig report 50 and 80 per cent for the two groups, respectively.

The delivery of normal infants after the appearance of erythroblastosis in the previous infant was observed in 4 patients (not primiparas). These infants had no special prenatal therapy nor was there a change in husbands. However, these mothers had had normal infants prior to the appearance of erythroblastosis.

Multiple pregnancy. Erythroblastosis has been reported in twins by Woolley, Oberdorfer, M. M. Mabon, Abt, B. Hurman and Sanford, and Andrew and Miller. V. terinarians have observed the hydrops in one of Bitter of pups. Sometimes one is normal, as in de Lange case. MackE found in her survey of the literature that when one had hydrops the other was normal in 8 out of 9 cases, whereas with icterus, both infants are so affected in 5 out of 7 cases. Unfortunately most of the reports fail to distinguish between identical or fraternal twins. This is of importance since erythroblastosis may be congenital disturbance affecting only one infant as in M. Mabon case of identical twins, whereas both of the monozygotic twins reported by Snyder and Ford had fetal hydrops.

Of our 47 cases, only one mother had single ovum twins (female) one of which was dead-born and macerated and had the unclassified type of erythroblastosis; the other died at the age of 2 days of congenital anemia, prematurity and cardiac hypertrophy. Other features of this case are as follows:

Cas. 2. Mrs. E. T. Hungaria, 26 years old, primigravida who had a normal pregnancy. The diagnosis of twins having been confirmed by x-ray. The Wassermann was negative. Labor began spontaneously in the third-eighth week of gestation, and after 9 hours labor I A weighing 50 grams, was delivered by breech extraction. It lived for 4 days and developed petechiae and convulsions. Examination of the cord blood at birth revealed red corpuscle count of 3,500,000, hemoglobin 5 grams, the white cell count, 55,000 and 20 erythroblasts and 95 normoblasts per 100 white cells. The cord prothrombin was 7 per cent of normal, the fibrinogen was 0.25 grams per cent (without evidence of hemorrhagic diathesis). During life 1 transfusion was given and milligrams of synthetic vitamin K (thyloquinone, Squibb). The infant died on the second day of life. The prime pathological features comprised large heart weighing 30 grams, hematopoiesis of the liver and spleen, with areas of focal necrosis in the former.

T 1. B was a dead-born and macerated female weighing 650 grams. A smear of cord blood showed 6 erythroblasts and 7 normoblasts per 100 white cells. The white cell count was 3,000. Since the blood was hemolyzed, no further studies were made. Autopsy revealed marked toxemia so that histological diagnosis could not be carried out. The placenta weighed 800 grams, and examination of the membranes confirmed the diagnosis of single ovum twins. Grossly the placenta revealed deeply stained membranes for twin B and histologically the outstanding criteria are the normoblasts in the fetal vessels.

The diagnosis of erythroblastosis of the unclassified type was made on twin B while twin A was considered as having the anemic form of the disease. It is probable that had twin B been born alive, it might have developed anemia or icterus and could then have been classified in the conventional manner.

Blood studies. Fifteen mothers (7 hydrops) had complete hematological examination including smear while the rest had an average of 1 or more hemoglobin determinations during the parturition course. All were within normal limits, save for mild anemia in cases Moore and Pastore have reported a case of erythroblastic splenomegaly in a mother who delivered normal infant. Doi reports the occurrence of erythroblastosis in the blood of

average weight in the icterus group was 3,442 grams, which agrees with the duration of 39 weeks' gestation. There was 1 premature child in this group.

Appearance at birth The hydropic child has marked pitting edema, the neck is short, and there is a suggestion of Mongoloid facies. The abdominal and thoracic distention is due to effusion and a large liver, and may be so marked that the natural posture of the child is prevented, causing it to assume a Buddha-like position, as was sometimes observed *intra uterum* by x-ray (Fig 10b). The arms and legs seem shorter than normal and the skin is usually macerated if the child is stillborn, as many of them are (Figs 1 and 3a). The vernix may have a yellow color. The child with the icterus form of erythroblastosis is usually born alive and may or may not be slightly yellow at birth, or become so soon thereafter (Fig 4, frontispiece). The child may require resuscitation. Liver and spleen are usually enlarged.

Congenital anomalies Such defects were found in 10 of the 47 infants, or 21 per cent, and included harelip and cleft palate, spina bifida, hydrocele, supernumerary fingers, cervical rib, urethral stricture, and an interventricular septal defect. Murphy gives the incidence of congenital defects in deceased liveborn and stillborn infants as 0.54 and 0.68 per cent, respectively, so that the incidence in our infants with erythroblastosis is approximately 40 times greater. Weber and Scholtz have described a case of hydrops fetalis that had multiple congenital anomalies, Vecchi's case had polydactylia and cystic kidneys, and the case reported by Bourret and Lathoud also had cystic kidneys. Murphy found that families possessing two or more malformations had subsequent offspring with the same deformity in 50 per cent of the infants. This corresponds closely to our incidence of 50 and 40 per cent for the hydrops and icterus cases, respectively, and to the 50 per cent incidence reported by Macklin. It seems from this evidence that any theory must consider the congenital aspect when used to explain the pathogenesis of erythroblastosis, enzymotic twins sometimes have the disease, which is further evidence of its congenital nature.

Symptoms in addition to hydrops and icterus The clinical differentiation of erythroblastosis into hydrops, icterus, anemia, and hemorrhagic forms may be difficult because of an overlapping of signs. For instance, a baby with hydrops may develop jaundice (Case 4), and an icteric infant may develop focal edema about the eyelids and scrotum, while both of these types may also have an associated anemia. They may also show evidence of hemorrhagic diathesis as a coexisting complication, or it may be the first evidence *per se* of erythroblastosis, as in Case 3. Finally, a few infants may die *in utero* (Case 2), or may not live long enough to develop any of the usual signs of hydrops, icterus, or anemia. Nevertheless, they may have erythroblastosis as we have observed in 4 cases, and these have been placed in an *unclassified* group, and have already been referred to.

Of the 25 infants born alive and having erythroblastosis, the following clinical signs were observed: focal edema in 16 cases, pallor in 12, skin petechiae in 16, visceral hemorrhages in 7, 3 of which were thought to be hemorrhagic disease until blood studies showed the erythroblastosis, cyanosis in 17, dyspnea in 10, convulsions in 4. Many infants had two or more of these signs in addition to the hydrops or icterus. The high incidence of hemorrhagic diathesis, 29 per cent, and skin petechiae, 64 per cent, indicates an increased capillary permeability. The usual incidence of hemorrhagic disease of the newborn has been shown by Javert and others to be only 0.7 per cent.

The following case illustrates the occurrence of melena as the first indication of erythroblastosis. This case is important in that the mother subsequently delivered an infant with erythroblastosis associated with hemorrhagic diathesis, and previously had delivered an infant with hydrops fetalis.

CASE 3 Mrs. P. S., aged 33, negro, parity 9-8-1-6, delivered a deadborn, macerated and edematous infant in her previous pregnancy, the autopsy showed erythroblastosis. The present pregnancy was complicated by a mild pre-eclampsia. She was delivered in the thirty-eighth week of gestation, after a 2½ hour labor, by breech extraction. This baby weighed 3,820 grams. Soon after birth it developed dyspnea, skin petechiae, facial twitchings, and had a large bloody stool. The liver and spleen were enlarged. The red blood cell count on the first day of life was 4,300,000, hemoglobin, 16 grams, white blood cells, 38,100, 140 nucleated red cells were counted per 100 white cells. Two transfusions were given in addition to supportive therapy, but slight edema of the extremities occurred and the child died 36 hours after birth. The chief pathology comprised erythroblastosis of the liver and spleen, with many nucleated red cells in the vessels. There was subarachnoid and cerebellar hemorrhage to which death was attributed. The placenta weighed 880 grams and was grossly unremarkable.

Two years later, this mother was delivered of her ninth full term child in the thirty-seventh week of gestation. Again she had a mild pre-eclampsia. This child weighed 4,580 grams. On the first day of life the white blood cell count was 42,000 and there were 4 erythroblasts and 98 normoblasts per 100 white cells. The red count was 6,000,000 for which reason only serum transfusions were given. The child developed slight edema, cyanosis, and many skin petechiae of the face and arms. He made an uneventful recovery.

Essential autopsy data In general, the hydrops cases showed a greater degree of erythroblastosis and erythroblastemia than did the icterus types, as shown by 29 complete postmortem examinations (88 per cent).

Fig. Roentgenograms showing hydrops fetalis in utero. (Retouched) a, left, Fetal head has "halo" due to edema of scalp. b, Habitus of fetus conforms to Boddian, or frog-like posture due to abdominal enlargement caused by ascites and large liver.

mothers with "pregnancy kidney and eclampsia. The Kline-Wassermann reaction was negative in 11 of the 47 cases. There was not the slightest indication of syphilis, which is of significance since the placenta was occasionally so diagnosed. The Rh⁺ agglutinin of Levine and Katzin was absent in several mothers.

The blood chemical constituents were studied in 9 mothers with the following average results per 100 cubic centimeters of blood:

	Mothers with erythroblastosis	Control at term (Standard)
Kempe's nitrogen	3 mgm.	48 mgm.
Urea-nitrogen	3.7 mgm.	mgm.
Uric acid	3 mgm.	3 mgm.
Chlorides	3.3 mgm.	44.4 mgm.
Sugar	3 mgm.	80 mgm.
Carbon dioxide combining power	35 vol. %	5 vol. %
Icterus index	9-9 units	0-3 units

The chief deviation from normal was seen in the blood uric acid and carbon dioxide combining power which was explained by the presence of toxemia in most of the mothers studied. The icterus index was also elevated, and ranged from 3 to 20 units in 7 mothers with hydrops, and averaged 5 units in 3 mothers having infants with icterus gravis (normal 1-3 units). The icterus index of the cord blood of

Rh⁺ was negative present in the red cells of all Macaca rhesus monkeys (hence the name), and in 100 per cent of human blood, while 100 per cent of the population at large is Rh negative. According to Levine (personal communication), 90 per cent of the mothers having infants with erythroblastosis are Rh negative. The blood of the fathers and the placenta usually Rh positive.

the infants was 9 units and 66 units for the two types, respectively (normal 1 to 5 units). Ten mothers had clinical jaundice and Buhman and Sanford observed it in one of their cases in the last month of pregnancy. It is due either to diffusion of bilirubin from the infant through the placenta into the maternal circulation, or to the maternal liver dysfunction, or both of these factors.

The serum proteins were studied in 3 mothers and the average of determinations was 5.0 grams per 100 cubic centimeters which is below the normal for pregnant patient at term. Case had as little as 3.4 grams, and she delivered an infant with hydrops that had .9 grams per 100 cubic centimeters. Prothrombin determinations in which the technique of Warner, Brinkhous and Smith were used, showed varying concentrations ranging from 20 to 100 per cent.

Mortality. All of the 47 mothers survived.

INFANTS DATA

These are presented for the most part on the basis of 16 cases of the hydrops and 22 cases of the icterus gravis types of erythroblastosis.

Sex. In the hydrops group, there were 9 males and 7 females, whereas in the icterus group there was preponderance of males, 4 to 8.

Birth weight. The average weight of the hydrops group was 3,420 grams, which is 1,000 grams more than for the average of 36 weeks gestation. The

wood, Strong and Marks, and others have associated icterus gravis as a possible forerunner of hepatolenticular degeneration

The epiphyseal line was described as normal in some cases and widened in others, which may indicate metabolic disturbance. There were no histological or roentgenological evidences of syphilis. The bone marrow was hyperplastic and contained many immature cells of the red and white series in varying degrees of maturation (Fig 7b). The persistence of hematopoietic foci in the liver and organs as well as the bone marrow hyperplasia certainly indicate that there is no lack of antianemic principle required for red cell maturation. It is possible that the immature red cells enter the circulation from the foci located in the various organs and not only from the bone marrow.

Heart blood cultures These were obtained in 18 infants and were negative in all, confirming the studies of Abt, Diamond and his co workers, and ruling out sepsis neonatorum.

Cord blood studies These were made on 5 hydrops cases and 3 infants with icterus gravis, while 11 infants of the latter group were studied on the first day of life and are, therefore, comparable to the cord blood studies. The average of the findings are as follows:

	RCC	Hgb (gms)	CV	WCC	NRC	Index
5 Hydrops cases	1.51	5.5	25	54.3	37.6	1.5 1.3
3 Icterus cases	3.50	14.7	52	47.0	21.2	1.3 1.4
11 Icterus cases on first day of life	3.1	13.6		37.2	18.5	1.4

Cord blood studies in erythroblastosis are seldom described in the literature. We have studied smears of cord blood in 9 cases of hydrops and 6 cases of icterus. The average results of these studies are:

	Normo- blasts	Erythro- blasts	Reticulo- cytes	Immature polymor- phonuclears	Immature lympho- cytes	Red cell diameter
9 Hydrops	30.4	9.8	7.1%	34	16	0.54
6 Icterus	7.1	14		10	0	0.50

The hydrops cases showed marked macrocytosis and polychromasia, with numerous erythroblasts and normoblasts, mitotic figures, and reticulocytes (Fig 8). The immature polymorphonuclear cells were abundant as were lymphoblasts, which confirms the findings of Diamond, Blackfan, and Baty. The volume index (normal 1.08) and color index (normal 1.2) were very much increased in both groups. The mean corpuscular diameter (normal 8.5 μ) was not increased in the icterus group, but was markedly so in the hydrops infants (10.5 μ). The macrocytosis

suggests liver damage or insufficiency, for Kracke and Garver, and others find liver disease complicated by a macrocytic anemia. The ratio of normoblasts to erythroblasts in the hydrops group was 3.8:1, and 5:1 in the icterus group. In normal pre-mature infants, according to Javert, it is 6.6:1, and in full term infants 14:1.

The blood studies vary greatly with the clinical type of the disease. In the hydrops type, the red cell count may be as low as 500,000 per cubic millimeter. The nucleated red cells are acetic acid resistant and are, therefore, present in the counting chamber as "white cells," and may number up to 300,000 per cubic millimeter.

Smears stained by the Wright technique (Fig 9, frontispiece) reveal megalocytic erythroblasts with large nuclei containing a lacy chromatin network and several nucleoli, with a cytoplasm which is basophilic since hemoglobin is deficient or absent. Mitotic figures are frequent. The normoblasts are smaller and approach the red cell in size. They have a cytoplasm which is less basophilic, and the nuclei are smaller and pyknotic. The degree of erythroblastemia varies with the hydrops or icterus types, being more pronounced in the former.

The degree of erythroblastosis seems to control the severity of erythroblastemia, for in the hydrops type in which both are most pronounced, a great many immature red cells—erythroblasts—can be found in the circulating blood. In the icteric form, nucleated red cells are fewer in number and are more mature—normoblasts—while in the anemic form of the disease these cells are even more mature—reticulocytes and normoblasts. Consequently, it is probable that the hematopoietic foci as well as the hyperplastic bone marrow liberate these cells.

In the icterus cases that survived, there was a gradual decrease in the number of nucleated red cells so that in the first week to 10 days of life, they had virtually disappeared from the circulating blood. Therefore, the diagnosis had best be made hematologically at birth or soon thereafter, for it may be missed as in one of our cases in which a normal blood smear was made on the tenth day of life but autopsy revealed unmistakable evidence of erythroblastosis. The rate of disappearance may have prognostic value. Case 4, an infant with hy-

The chief deviation from normal, in addition to the hydrops or icterus, was seen in the heart, liver and spleen (Fig 3b). The heart was invariably hypertrophied, and in some cases weighed 40 grams. This hypertrophy caused fetal distress as well as cardiac murmurs, which were heard in 3 infants with icterus and 6 with hydrops and of the latter 3 were heard *intra utero*. Histological section of the heart muscle usually showed vacuolization due to the edematous infiltration.

The liver and spleen were invariably increased in weight and on histological examination numerous hematopoietic foci and sinusoids were seen filled with immature red and white cells (Fig 5 frontispiece). The foci were often more numerous in the hydrops cases, and have been regarded by Abt as a persistence of embryonal blood formation. Since these infants were more immature than the icterus gravis cases, we feel that prematurity may be sufficient to explain the difference. Deposits of pigment could be seen in the Kupffer and liver cells in the hydrops cases (Fig 6 frontispiece). The pigment is stained blue in some cells and remains brown in others. This may represent hemoglobin of fetal and adult origin as suggested by Darrow, Nowakovsky and Austin. The icterus cases usually had no intracellular pigment, but had instead numerous bile thrombi. The livers of several deadborn infants were so autolyzed that histological study was impossible yet the pigment was readily observed. Its presence may prove of diagnostic importance when tissues are extremely macerated. Many livers showed varying degrees of cloudy swelling, fatty degeneration, or necrosis (Fig 7a) and these changes together with the intracellular pigment and hematopoietic foci, which constituted from 10 to 40 per cent of the liver structure made up a liver parenchyma of greatly impaired functional capacity. Degeneration is observed in the livers of infants dying of other causes, but its presence in erythroblastosis, in addition to the hematopoietic foci and intracellular pigment, would speak for impaired hepatic function if the postmortem changes could be definitely ruled out. In general the histological changes were most marked in the hydrops group. De Lange

and Arntzenius found cases without degeneration of the liver as we have also observed while others, including Klempeter and Hawkey and Lightwood, have described the degenerative changes. Subsequent juvenile cirrhosis of the liver may be traceable to icterus gravis according to Boynton and Wyllie. Brink and Ebbs, while Wilson has associated hepatic degeneration with pathology of the lenticular nuclei. Cirrhosis of the liver may be associated with low serum proteins, edema and death, as reported in a 2½ year old girl by Thompson, Ziegler and McQuarrie. Hypoproteinemia has been regarded by Weech and others as the result of severe liver damage.

Hematopoiesis was usually evident in other organs including the kidney, adrenal, thymus, thyroid, pancreas, and various lymph nodes. The degree of involvement was greatest in the hydrops cases. The kidney sometimes showed cloudy swelling and tubular degeneration in addition to deposits of pigment, which may handicap the child after birth when excretion by the placental route is no longer present.

The serous cavities usually contained amber colored fluid in varying amounts, and this was most marked in the hydrops cases. The abdominal cavity at times contained up to 150 cubic centimeters of amber colored fluid.

Petechial hemorrhages were often seen in the internal organs which, together with the clinical evidence of skin petechiae and hemorrhage diathesis, may be attributed to impaired capillary permeability.

Kernicterus, first described by Schmorl, was observed in 5 or 45 per cent of the icterus cases and in none of the 9 hydrops cases that came to autopsy. The basal nuclei of the brain particularly the optic thalamus, olivary bodies and the dentate and lenticular nuclei were involved. Two of the 5 cases that showed the condition had convulsions with no sign of intracranial hemorrhage. Zimmerman and Yannett described a child of 3 years with a history of icterus gravis who had residual spasticity and mental retardation. Degeneration of the basal nuclei was found at autopsy and the possible relation to kernicterus was emphasized. The association of lenticular degeneration and liver cirrhosis was made by Wilson in 1912. Parsons, Hawkey and Light

wood, Strong and Marks, and others have associated icterus gravis as a possible forerunner of hepatolenticular degeneration

The epiphyseal line was described as normal in some cases and widened in others, which may indicate metabolic disturbance. There were no histological or roentgenological evidences of syphilis. The bone marrow was hyperplastic and contained many immature cells of the red and white series in varying degrees of maturation (Fig 7b). The persistence of hematopoietic foci in the liver and organs as well as the bone marrow hyperplasia certainly indicate that there is no lack of antianemic principle required for red cell maturation. It is possible that the immature red cells enter the circulation from the foci located in the various organs and not only from the bone marrow.

Heart blood cultures These were obtained in 18 infants and were negative in all, confirming the studies of Abt, Diamond and his co-workers, and ruling out sepsis neonatorum.

Cord blood studies These were made on 5 hydrops cases and 3 infants with icterus gravis, while 11 infants of the latter group were studied on the first day of life and are, therefore, comparable to the cord blood studies. The average of the findings are as follows:

	RCC	Hgb (gms)	CV	W.C.C.	NRC	Vol	Index Color
5 Hydrops cases	151	5.5	25	54.3	37.6	1.5	1.3
3 Icterus cases	356	14.7	52	42.0	21.2	1.3	1.4
11 Icterus cases on first day of life	31	13.6		37.2	18.5		1.4

Cord blood studies in erythroblastosis are seldom described in the literature. We have studied smears of cord blood in 9 cases of hydrops and 6 cases of icterus. The average results of these studies are:

	Normo- blasts	Erythro- blasts	Reticulo- cytes	Immature polymor- pho- nuclears	Imma- ture lympho- cytes	Red cell diam- eter
9 Hydrops	304	98	7.1%	34	16	9.5 μ
6 Icterus	71	14		10	0	8.0 μ

The hydrops cases showed marked macrocytosis and polychromasia, with numerous erythroblasts, normoblasts, mitotic figures, and reticulocytes (Fig 8). The immature polymorphonuclear cells were abundant, as were lymphoblasts, which confirms the findings of Diamond, Blackfan, and Baty. The volume index (normal 1.08) and color index (normal 1.2) were very much increased in both groups. The mean corpuscular diameter (normal 8.5 μ) was not increased in the icterus group, but was markedly so in the hydrops infants (9.5 μ). The macrocytosis

suggests liver damage or insufficiency, for Kracke and Garver, and others find liver disease complicated by a macrocytic anemia. The ratio of normoblasts to erythroblasts in the hydrops group was 3.8:1, and 5:1 in the icterus group. In normal premature infants, according to Javert, it is 6.6:1, and in full term infants 14:1.

The blood studies vary greatly with the clinical type of the disease. In the hydrops type, the red cell count may be as low as 500,000 per cubic millimeter. The nucleated red cells are acetic acid resistant and are, therefore, present in the counting chamber as "white cells," and may number up to 300,000 per cubic millimeter.

Smears stained by the Wright technique (Fig 9, frontispiece) reveal megalocytic erythroblasts with large nuclei containing a lacy chromatin network and several nucleoli, with a cytoplasm which is basophilic since hemoglobin is deficient or absent. Mitotic figures are frequent. The normoblasts are smaller and approach the red cell in size. They have a cytoplasm which is less basophilic, and the nuclei are smaller and pycnotic. The degree of erythroblastemia varies with the hydrops or icterus types, being more pronounced in the former.

The degree of erythroblastosis seems to control the severity of erythroblastemia, for in the hydrops type in which both are most pronounced, a great many immature red cells—erythroblasts—can be found in the circulating blood. In the icteric form, nucleated red cells are fewer in number and are more mature—normoblasts—while in the anemic form of the disease these cells are even more mature—reticulocytes and normoblasts. Consequently, it is probable that the hematopoietic foci as well as the hyperplastic bone marrow liberate these cells.

In the icterus cases that survived, there was a gradual decrease in the number of nucleated red cells so that in the first week to 10 days of life, they had virtually disappeared from the circulating blood. Therefore, the diagnosis had best be made hematologically at birth or soon thereafter, for it may be missed as in one of our cases in which a normal blood smear was made on the tenth day of life but autopsy revealed unmistakable evidence of erythroblastosis. The rate of disappearance may have prognostic value. Case 4, an infant with hy-

drops surviving 11 days, had 42 normoblasts per 100 white cells on the day of death.

Blood chemistry of fetus. The chemical constituents of the cord blood per 100 cubic centimeters is presented in the following table.

	Hydrops cases	Icterus cases	Control
Nonprotein nitrogen	(4) 41.7 mgm.	(3) 60 mgm.	35 mgm.
Uric acid	(4) 7.3 mgm.	(3) 3.8 mgm.	3 mgm.
Chlorides	(4) 503 mgm.	(3) 305.9 mgm.	500 mgm.
Serum proteins	(4) 3.8 gm.	(3) 3.3 gm.	3 gm.
Fibrinogen	(4) 67 gm.	(3) 67 gm.	67 gm.
Prothrombin	(4) 5%	(3) 7%	5%
Icterus index	(4) 91 units	(3) 60 units	18 units

(Figures in parentheses denote number of cases studied)

The increased values in the nonprotein nitrogen and uric acid may accompany the higher values observed in the mothers, caused by the pre-eclamptic type of toxemia. The chlorides were elevated in the hydrops group. The serum proteins were decreased in both the hydrops and icterus cases, but to greater extent in the former and in case were as low as .4 grams. The hypoproteinemia is thought to be the result of liver damage which was the greatest in the hydrops group. Weech has found lowered serum proteins following impairment of liver function in other conditions and in case of congenital syphilis.

The prothrombin concentration of the cord blood was studied in 7 cases of erythroblastosis and an average level of between 3 and 7 per cent of normal was obtained. The lowest values were observed in cases with hydrops. The Warner Brinkhous, and Smith test was employed and, as Jvert and Moore have shown, the prothrombin concentration of cord blood is normally about 3 per cent of the adult normal. The hypoprothrombinemia, the lowered serum proteins, the edema and hemorrhagic diathesis, all speak of impaired capillary permeability and may be associated with impaired liver function, being most marked in the hydrops cases.

Rh factor. Determinations made by Levin in 6 cases showed the cord blood to be Rh positive in all. The blood of the fathers and mothers were Rh positive and negative respectively with one exception which will be reported elsewhere.

Differential diagnosis. In addition to the classification of erythroblastosis neonatorum as to type, it is necessary to rule out the following conditions: approximate order of frequency physiological jaundice, prematurity, intracranial hemorrhage, hemorrhagic disease of the newborn, congenital heart disease, congenital syphilis, sepsis neonatorum, obstruction of the bile ducts, familial acholic jaundice, Winckel disease and hypoproteinemia.

Treatment. In addition to the supportive measures such as oxygen infusions and artificial feedings repeated transfusions were given. As many as 9 transfusions, averaging 60 cubic centimeters in amount, were given in the first days of life. We agree with Arnold

and Downey who state that the physician who fails to give enough blood is able to make complete case reports including the autopsy protocol. Hampson has used intramuscular whole blood in icterus gravis with good results which Hawkeley and Lightwood failed to duplicate. The value of whole blood by vein and intramuscularly in addition to the cellular elements may be due in part also to the protein and prothrombin content. For this reason vitamin K may be of value, and we have used it in several cases. The transfusions were given with blood from donors that were compatible. Since the blood of the infants is Rh positive tests for this factor may also be indicated.

Fetal mortality. In 1937 the author first directed attention to erythroblastosis as an important cause of fetal mortality stating that it was 3½ times greater than syphilis. It is responsible for more fetal deaths than asphyxia neonatorum, hemorrhagic disease of the newborn and toxemia of pregnancy. Macklin, Potter and others have since written on the rôle of erythroblastosis in infantile mortality. In a study of 750 fetal deaths in infants weighing over 1500 grams, including stillbirth and neonatal deaths up to the fourteenth day of life 3.2 per cent were caused by erythroblastosis and 1.3 per cent were due to syphilis. Syphilis as such has been overrated as a cause of stillbirths.

The fetal mortality rate in our 47 cases varied with the type of erythroblastosis encountered. Of this number 70 per cent perished.

Type of erythroblastosis	Still or dead-born	Non-fatal	Number of deaths Total	Percentage
Hydrops (6 cases)	—	7	16	100
Icterus (21 cases)	—	—	—	54
Aplasia (3 cases)	—	—	—	33
Hemorrhagic diathesis (3 cases)	—	—	—	33
Unclassified (3 cases)	—	—	3	100
Total	—	—	22	79

The mortality rate was 100 per cent in the hydrops cases although infant survived for period of days (Case 4). The rate for the icterus cases is about 50 per cent, which agrees with the observations of Hellman and Hertig. Of the unclassified cases, death was due to prolonged and intrapartum infection in cases like the third case as one of them here reported (Case 5).

The following case is unusual in that the infant with hydrops fetalis survived 11 days Wolfe and Neigus report 6 days, Hellman and Hertig 2 days, as the longest period of survival

CASE 4 Mrs D T, aged 31 years, American Hebrew, parity 2-0-3-2, in whom two spontaneous abortions occurred between her first and last full term infants, which are alive and well. The present pregnancy was complicated by "hydramnios", the uterus measured 39 centimeters at term (41 weeks gestation). Delivery was effected with forceps, the indication for which was fetal distress in the second stage of labor. The baby was excessive in size, weighing 4,380 grams, part of which was due to subcutaneous edema. The child required simple resuscitation at birth. The placenta weighed 1,760 grams. No histological section was made. The amniotic fluid was described as greenish yellow. The mother sustained a blood loss in the third stage of 660 cubic centimeters, part of which was due to a laceration into the right broad ligament because of dystocia due to difficulty with the shoulders.

Because of the edema of the infant, hematological studies were made at once. The red count was 5,200,000 per cubic millimeter, hemoglobin, 14.6 grams, white count 6,400, of which 3,400 were nucleated red cells, 86 nucleated erythrocytes, including erythroblasts, were counted per 100 white cells. The bleeding and clotting times were normal. On the subsequent day the serum proteins were 5.0 grams per 100 cubic centimeters, the blood calcium was 11.6, phosphorus 6.5, cholesterol 131, urea nitrogen 33 milligrams, chlorides 591 milligrams per 100 cubic centimeters. On the third day of life, definite jaundice developed (icterus index 100) and the edema seemed to be increasing. Petechiae developed on the face, and attacks of dyspnea and cyanosis were frequent. In addition to the usual supportive measures, the child was given 8 transfusions (total 405 c.c. citrated blood) and despite this, the red blood cell count was 4,900,000 and the hemoglobin 14 grams on the day of death. Nucleated red cells persisted in the blood stream and on the day of death there were 42 nucleated red cells per 100 white cells in the circulating blood. The nucleated cells disappear in 4 days in normal infants according to Javert and about 10 days in infants with erythroblastosis. The rate of disappearance may have prognostic significance.

Autopsy revealed the presence of greenish yellow fluid in the pericardial (7 c.c.), pleural (10 c.c.) and abdominal (50 c.c.) cavities. The heart was enlarged, weighing 45 grams, the liver weighed 203 grams, the spleen 10 grams. The liver and spleen showed diffuse erythroblastosis, the liver having in addition, fatty degeneration and portal fibrosis. Hematopoietic foci were also seen in the adrenal and kidney. Petechial hemorrhages were observed in the heart, thymus, adrenal and lungs. The bone marrow showed erythroblastic and granulocytic hyperplasia. Blood culture and Kline reaction were negative.

ANTEPARTUM DIAGNOSIS

This study has been presented for the most part from the obstetrical point of view and only the pertinent pathological and pediatric features have been discussed. Our aim has been to feature certain criteria which may prove helpful in making a correct antepartum diagnosis. This has obvious importance in the obstetrical management of the mother. For instance, in Case 5 patient was very anxious for a cesarean section in order to give the child every opportunity for survival, for several physicians had so advised her. The presence of an infant with hydrops was proved and section was refused.

CASE 5 Mrs L H, aged 34 years, white, parity 2-0-2-0, with a history of two abortions and two previous infants with hydrops, was first seen in the twenty-eighth week of gestation. A hematological examination revealed a normocytic hypochromic anemia for which iron was prescribed. The serum proteins were reduced and averaged 5.2 grams per 100 cubic centimeters, the plasma fibrinogen was only 0.3 gram per 100 cubic centimeters, while the prothrombin was 100 per cent of normal. The patient was placed on a high protein diet, rich in vitamins.

In the thirty-fifth week of pregnancy, the height of the uterus measured 36 centimeters and "hydramnios" was suspected. At this time a fetal bruit became evident. The patient remarked that the fetal activity was not great. Ankle edema became a prominent sign and a low protein diet was ordered. There was a gain of 4 kilograms in the following week. The blood pressure, which had been normal previously, rose suddenly to 170/100 and remained at that level, while albuminuria developed. At this time, the patient was hospitalized for study and treatment. The blood chemical findings included a uric acid reading of 7.4 milligrams per 100 cubic centimeters and a carbon dioxide combining power of 36.2 volumes per cent. Intravenous glucose was given. An x-ray examination of the fetus was made, a soft tissue technique being used in order to show soft tissue edema. A suggestive halo was observed about the child's head. However, the Buddha or frog-like posture of the infant was found to be more definite (see Fig 10b).

In the meantime, the maternal blood pressure increased to 180/110, the albuminuria persisted although the edema improved. In view of the toxemia and the increased hazard to the infant, the patient and her husband clamored for delivery by cesarean section. However, by this time sufficient data had been collected, namely, obstetrical history, hydramnios, fetal heart murmur, toxemia, and x-ray evidence of edema in the infant, all of which pointed to a diagnosis of erythroblastosis fetalis of the

drops surviving 11 days, had 43 normoblasts per 100 white cells on the day of death.

Blood chemistry of the fetus. The chemical constituents of the cord blood per 100 cubic centimeters is presented in the following table:

	Hydrops cases	Icterus cases	Control
Nonprotein nitrogen	(4) 4.1 mgm.	(1) 6.0 mgm.	3.5 mgm.
Uric acid	(4) 7.8 mgm.	(1) 2.8 mgm.	3 mgm.
Chlorides	(4) 50.1 mgm.	(1) 30.0 mgm.	50.0 mgm.
Serum proteins	(4) 3.8 gm.	(1) 3.2 gm.	3.9 gm.
Fibrinogen	(4) 0.6 gm.	(1) 0.7 gm.	1.0 gm.
Prothrombin	(4) 5%	(1) 7%	1 gm.
Icterus index	(7) 97 units	(1) 68 units	10 units

(Figures in parentheses denote number of cases studied)

The increased values in the nonprotein nitrogen and uric acid may accompany the higher values observed in the mothers, caused by the pre-eclamptic type of toxemia. The chlorides are elevated in the hydrops group. The serum proteins were decreased in both the hydrops and icterus cases, but to a greater extent in the former and in 1 case were as low as 1.4 grams. The hypoproteinemia is thought to be the result of liver damage which was the greatest in the hydrops group. Weech has found lowered serum proteins following impairment of liver function in other conditions, and in a case of congenital syphilis.

The prothrombin concentration of the cord blood was studied in 7 cases of erythroblastosis and an average level of between 3 and 7 per cent of normal as obtained. The lowest values were observed in cases with hydrops. The Warner, Brinkhous and Smith test was employed and, as Jervet and Moore have shown, the prothrombin concentration of cord blood is normally about 3 per cent of the adult normal. The hypoprothrombinemia, the lowered serum proteins, the edema and hemorrhagic diathesis, all speak for impaired capillary permeability and may be associated with impaired liver function, being most marked in the hydrops cases.

Rh factor. Determinations made by Levin in 6 cases showed the cord blood to be Rh positive in all. The blood of the fathers and mothers were Rh positive and negative respectively with one exception which will be reported elsewhere.

Differential diagnosis. In addition to the classification of erythroblastosis neonatorum as 1 type, it is necessary to rule out the following conditions in approximate order of frequency: physiological jaundice, prematurity, intracranial hemorrhage, hemorrhagic disease of the newborn, congenital heart disease, congenital syphilis, sepsis, neonatorum, obstruction of the bile ducts, familial cholemic jaundice, Winkler disease and hypoproteinemia.

Treatment. In addition to the supportive measures such as oxygen infusions and artificial feedings, repeated transfusions were given. As many as 9 transfusions, averaging 60 cubic centimeters in amount, were given in the first days of life. We agree with Arnold

and Downey who state that the physician who fails to give enough blood is able to make complete case reports including the autopsy protocol. Hampeon has used intramuscular whole blood in icterus gravis with good results which Hawkeley and Lightwood failed to duplicate. The value of whole blood by vein and intramuscularly in addition to the cellular elements may be due in part also to the protein and prothrombin content. For this reason vitamin K may be of value, and we have used it in several cases. The transfusions were given with blood from donors that were compatible. Since the blood of the infants is Rh positive, tests for this factor may also be indicated.

Fetal mortality. In 1937 the author first directed attention to erythroblastosis as an important cause of fetal mortality, stating that it was 2½ times greater than syphilis. It is responsible for more fetal deaths than asphyxia neonatorum, hemorrhagic disease of the newborn, and toxemia of pregnancy. Macklin, Potter and others have since written on the rôle of erythroblastosis in infantile mortality. In a study of 750 fetal deaths in infants weighing over 1500 grams, including stillbirth and neonatal deaths up to the fourteenth day of life, 3.2 per cent were caused by erythroblastosis and 1.3 per cent were due to syphilis. Syphilis as such has been overrated as a cause of stillbirths.

The fetal mortality rate in our 47 cases varied with the type of erythroblastosis encountered. Of this number 70 per cent perished.

Type of erythroblastosis	Still or dead here	Number of deaths	Percent
Hydrops (16 cases)	—	6	100
Icterus (1 case)	—	1	54
Anemia (3 cases)	—	3	33
Hemorrhagic diathesis (3 cases)	—	3	33
Unclassified (1 case)	—	1	100
Total	—	13	70

The mortality rate was 100 per cent in the hydrops cases although all 16 survived in a period of 11 days (Case 4). The rate for the icterus cases is about 50 per cent, which agrees with the observations of Hoffman and Hertig. Of the unclassified cases, death was due to prolonged cord and intrapartum infection in cases like the third case as one of them has been reported (Case 5).

The following case is unusual in that the infant with hydrops fetalis survived 11 days. Wolfe and Neigus report 6 days, Hellman and Hertig 2 days, as the longest period of survival.

CASE 4 Mrs D T, aged 31 years, American Hebrew, parity 2-0-3-2, in whom two spontaneous abortions occurred between her first and last full term infants, which are alive and well. The present pregnancy was complicated by "hydramnios", the uterus measured 39 centimeters at term (41 weeks gestation). Delivery was effected with forceps, the indication for which was fetal distress in the second stage of labor. The baby was excessive in size, weighing 4,380 grams, part of which was due to subcutaneous edema. The child required simple resuscitation at birth. The placenta weighed 1,760 grams. No histological section was made. The amniotic fluid was described as greenish yellow. The mother sustained a blood loss in the third stage of 660 cubic centimeters, part of which was due to a laceration into the right broad ligament because of dystocia due to difficulty with the shoulders.

Because of the edema of the infant, hematological studies were made at once. The red count was 5,200,000 per cubic millimeter, hemoglobin, 14.6 grams, white count 6,400, of which 3,400 were nucleated red cells, 86 nucleated erythrocytes, including erythroblasts, were counted per 100 white cells. The bleeding and clotting times were normal. On the subsequent day the serum proteins were 5.0 grams per 100 cubic centimeters, the blood calcium was 11.6, phosphorus 6.5, cholesterol 131, urea nitrogen 33 milligrams, chlorides 591 milligrams per 100 cubic centimeters. On the third day of life, definite jaundice developed (icterus index 100) and the edema seemed to be increasing. Petechiae developed on the face, and attacks of dyspnea and cyanosis were frequent. In addition to the usual supportive measures, the child was given 8 transfusions (total 405 c cm citrated blood) and despite this, the red blood cell count was 4,900,000 and the hemoglobin 14 grams on the day of death. Nucleated red cells persisted in the blood stream and on the day of death there were 42 nucleated red cells per 100 white cells in the circulating blood. The nucleated cells disappear in 4 days in normal infants according to Javert and about 10 days in infants with erythroblastosis. The rate of disappearance may have prognostic significance.

Autopsy revealed the presence of greenish yellow fluid in the pericardial (7 c cm), pleural (10 c cm) and abdominal (50 c cm) cavities. The heart was enlarged, weighing 45 grams, the liver weighed 203 grams, the spleen 10 grams. The liver and spleen showed diffuse erythroblastosis, the liver having in addition, fatty degeneration and portal fibrosis. Hematopoietic foci were also seen in the adrenal and kidney. Petechial hemorrhages were observed in the heart, thymus, adrenal and lungs. The bone marrow showed erythroblastic and granulocytic hyperplasia. Blood culture and *Kline reaction* were negative.

ANTEPARTUM DIAGNOSIS

This study has been presented for the most part from the obstetrical point of view and only the pertinent pathological and pediatric features have been discussed. Our aim has been to feature certain criteria which may prove helpful in making a correct antepartum diagnosis. This has obvious importance in the obstetrical management of the mother. For instance, in Case 5 patient was very anxious for a cesarean section in order to give the child every opportunity for survival, for several physicians had so advised her. The presence of an infant with hydrops was proved and section was refused.

CASE 5 Mrs L H, aged 34 years, white, parity 2-0-2-0, with a history of two abortions and two previous infants with hydrops, was first seen in the twenty-eighth week of gestation. A hematological examination revealed a normocytic hypochromic anemia for which iron was prescribed. The serum proteins were reduced and averaged 5.2 grams per 100 cubic centimeters, the plasma fibrinogen was only 0.3 gram per 100 cubic centimeters, while the prothrombin was 100 per cent of normal. The patient was placed on a high protein diet, rich in vitamins.

In the thirty-fifth week of pregnancy, the height of the uterus measured 36 centimeters and "hydramnios" was suspected. At this time a fetal bruit became evident. The patient remarked that the fetal activity was not great. Ankle edema became a prominent sign and a low protein diet was ordered. There was a gain of 4 kilograms in the following week. The blood pressure, which had been normal previously, rose suddenly to 170/100 and remained at that level, while albuminuria developed. At this time, the patient was hospitalized for study and treatment. The blood chemical findings included a uric acid reading of 7.4 milligrams per 100 cubic centimeters and a carbon dioxide combining power of 36.2 volumes per cent. Intravenous glucose was given. An x-ray examination of the fetus was made, a soft tissue technique being used in order to show soft tissue edema. A suggestive halo was observed about the child's head. However, the Buddha or frog-like posture of the infant was found to be more definite (see Fig. 10b).

In the meantime, the maternal blood pressure increased to 180/110, the albuminuria persisted although the edema improved. In view of the toxemia and the increased hazard to the infant, the patient and her husband clamored for delivery by cesarean section. However, by this time sufficient data had been collected, namely, obstetrical history, hydramnios, fetal heart murmur, toxemia, and x-ray evidence of edema in the infant, all of which pointed to a diagnosis of erythroblastosis fetalis of the

drops surviving 11 days, had 42 normoblasts per 100 white cells on the day of death.

Blood chemistry of the fetus. The chemical constituents of the cord blood per 100 cubic centimeters is presented in the following table:

	Hydrops cases	Icterus cases	Control
Nonprotein nitrogen	(4) 41.7 mgm.	(3) 60 mgm.	35 mgm.
Uric acid	(3) 7.8 mgm.	(3) 3.8 mgm.	2.1 mgm.
Chlorides	(3) 28.8 mgm.	(3) 26.0 mgm.	500 mgm.
Serum proteins	(3) 3.8 gm.	(3) 5.3 gm.	5 gm.
Fibrinogen	(3) 6.9 gm.	(3) 0.2 gm.	1 gm.
Prothrombin	(3) 5%	(3) 7%	1 gm.
Icterus index	(3) 91 units	(3) 66 units	1 unit

(Figures in parentheses denote number of cases studied)

The increased values in the nonprotein nitrogen and uric acid may accompany the higher values observed in the mothers caused by the pre-eclamptic type of toxemia. The chlorides are elevated in the hydrops group. The serum proteins were decreased in both the hydrops and icterus cases, but to a greater extent in the former and in the latter case were as low as 1.4 grams. The hypoproteinemia is thought to be the result of liver damage which was the greatest in the hydrops group. Weech has found lowered serum proteins following impairment of liver function in other conditions, and in case of congenital syphilis.

The prothrombin concentration of the cord blood was studied in 7 cases of erythroblastosis and average level of between 3 and 7 per cent of normal was obtained. The lowest values are observed in cases with hydrops. The Warner, Brinkhouse, and Smith test was employed and, as Jervet and Moore have shown, the prothrombin concentration of cord blood is normally about 3 per cent of the adult normal. The hypoprothrombinemia, the lowered serum proteins, the edema and hemorrhagic diathesis, all speak for impaired capillary permeability and may be associated with impaired liver function, being most marked in the hydrops cases.

Rh factor. Determinations made by Levine in 6 cases showed the cord blood to be Rh positive in all. The blood of the fathers and mothers were Rh positive and negative respectively, with one exception which will be reported elsewhere.

Differential diagnosis. In addition to the classification of erythroblastosis neonatorum as type I, it is necessary to rule out the following conditions in approximate order of frequency: physiological jaundice, prematurity, intracranial hemorrhage, hemorrhagic disease of the newborn, congenital heart disease, congenital syphilis, sepsis neonatorum, obliteration of the bile ducts, familial acholuric jaundice, Winkler disease and hypoproteinemia.

Treatment. In addition to the supportive measures such as oxygen infusions and artificial feedings repeated transfusions were given. As many as 9 transfusions averaging 60 cubic centimeters in amount, were given in the first days of life. We agree with Arnold

and Downey who state that the physician who fails to give enough blood is able to make complete case reports including the autopsy protocol. Hampson has used intramuscular whole blood in icterus gravis with good results which Hawkeley and Lightwood failed to duplicate. The value of whole blood by vein and intramuscularly in addition to the cellular elements may be due in part also to the protein and prothrombin content. For this reason vitamin K may be of value and we have used it in several cases. The transfusions were given with blood from donors that were compatible. Since the blood of the infants is Rh positive tests for this factor may also be indicated.

Fetal mortality. In 1937 the author first directed attention to erythroblastosis as an important cause of fetal mortality stating that it was 2½ times greater than syphilis. It is responsible for more fetal deaths than asphyxia neonatorum, hemorrhagic disease of the newborn and toxemia of pregnancy. Macklin, Potter and others have since written on the role of erythroblastosis in infantile mortality. In a study of 750 fetal deaths in infants weighing over 1500 grams, including stillbirth and neonatal deaths up to the fourteenth day of life, 32 per cent were caused by erythroblastosis and 13 per cent were due to syphilis. Syphilis as such has been overrated as a cause of stillbirths.

The fetal mortality rate in our 47 cases varied with the type of erythroblastosis encountered. Of this number 70 per cent perished.

Type of erythroblastosis	Still or dead-born	Non-fatal	Total	Percentage
Hydrops (6 cases)	—	—	100	100
Icterus (4 cases)	—	—	54	54
Asymptomatic (3 cases)	—	—	33	33
Hemorrhagic diathesis (3 cases)	—	—	33	33
Unclassified (3 cases)	—	—	3	100
Total	—	—	33	70

The mortality rate was 100 per cent in the hydrops cases although 1 infant survived for a period of 11 days (Case 4). The rate for the icterus cases is about 50 per cent, which agrees with the observations of Hellman and Hertig. Of the unclassified cases, death was due to prolonged cord and intrapartum infection in 2 cases, while the third case was one of twins here reported (Case 9).

hydrops type. The parents request for cesarean section was refused. Instead, the membranes were ruptured artificially (the uterus being very irritable) and after short labor of 6 hours, midforceps delivery was effected with the pediatrician in attendance. The placenta was very large and edematous with a pale maternal surface, very friable, and was delivered with difficulty because of its large size (100 grams). A blood loss of 500 cubic centimeters was sustained in the third stage of labor. Postpartum course was uncomplicated.

The child weighed 3,020 grams (exclusive for 37 weeks gestation) part of which was due to marked generalized edema. It lived for 3 minutes during which time resuscitation with carbon-dioxide-oxygen mixture was carried out. Fluid was also aspirated from the thorax and abdomen to remove these obstacles to respiration, and blood was obtained from the cord for cross matching and blood studies. The red cell count was 2,000,000 per cubic millimeter, hemoglobin 3 per cent (Sahli) white cell count 9,600 per cubic millimeter of which 6,93 were nucleated red cells. The red cell volume was 3 millimeters per cent. The volume index was 6 and the color index .5 and the mean corpuscular diameter was 0.7μ . In the stained smear 3 normoblasts and 3 erythroblasts were counted per 100 white cells. Many of the latter were immature, and 6 per cent of the red cells were reticulocytes. The plasma prothrombin was less than 5 per cent of normal, the serum proteins were only .45 grams, and the nonprotein nitrogen was 4.7 and the uric acid 7.8 milligrams per 100 cubic centimeters. The liver index was 75 mlts. Autopsy and histological examination confirmed the diagnosis of erythroblastosis fetalis.

This patient became pregnant 6 months later and a therapeutic abortion was performed because of residual renal and liver damage following the severe pre-eclampsia. The history of 3 infants with erythroblastosis may have contributed to the decision to terminate the pregnancy although it was not used as the indication. At this time studies of the Rh factor revealed the mother to be negative and the father to be positive. The patient has since adopted a child. This case also illustrates the gloomy obstetrical future of primiparas having a firstborn infant with erythroblastosis as discussed above under Familial History.

There are cases that have a normal course until labor begins and then developments occur such as loss of fetal movement, irregular fetal heart, premature rupture of the membranes with escape of yellow fluid, etc., which should arouse suspicion. Diagnosis at this

stage of pregnancy is illustrated by the following case referred to in the preliminary report of this study made in 1937.

CASE 6. Mrs. N. J. was a 29 year old Armenian woman, parity 0-0-1 with a negative Wassermann. The pregnancy was uneventful until the thirty-sixth week of gestation when the membranes ruptured prematurely and it was observed that the fluid had a golden yellow color. The head was dipping well into the pelvis the cervix was closed and there were no uterine contractions. The fetal heart was slow with a rate of 60 to 80 per minute. As contractions developed, the rate increased. However rectal ether without quinine was given in order to relax the uterus between pains. Spontaneous delivery occurred after labor of 9 hours.

The infant was a female weighing 3,341 grams. The vernix had a golden yellow color and the child had a suggestive Mongoloid appearance. There was localized edema of the eyelids. Resuscitation with carbon-dioxide-oxygen mixture was necessary. The cord blood was promptly studied and 80 normoblasts and 20 erythroblasts were counted for 100 white cells. The red count was 5,600,000 and the white count 80,000 of which 20,000 are nucleated red cells. Despite prompt diagnosis and transfusion of 60 cubic centimeters of compatible blood, the infant died 3 hours after delivery. Autopsy confirmed the clinical diagnosis. The placenta weighed 660 grams, had marked yellow color of the membranes, and histologically was remarkable only in that the nucleated red cells were increased in the fetal vessels.

A correct antepartum diagnosis of erythroblastosis neonatorum was made correctly by the author in 8 out of 10 cases. The signs having the greatest value in the 10 cases in which intrauterine diagnosis was attempted are as follows: multiparity 10 cases, excessive uterine enlargement (hydramnios) 6, amniotic fluid, yellow-brown, 6, premature labor 6, nationality (Irish) 6, icterus index increased, 5, erythroblastosis in a previous infant, 4, toxemia of pregnancy 4, fetal distress, before or during labor 3, intrauterine death of the fetus, 3, systolic bruit of fetal heart heard in the uterus, 3, aspiration of cord blood before delivery (prolapsed cord) 1, x-ray examination of fetus while within the uterus (7 cases studied) 2.

To recapitulate, multiparity and excessive uterine enlargement beyond the duration of gestation were valuable criteria, while the previous obstetrical history was less important. The x-ray was found to be among the

JAVERT ERYTHROBLASTOSIS NEONATORUM

least valuable aids Its use is limited to the hydrops cases We took our first roentgenogram in May, 1936, in an effort to detect edema of the scalp It was not successful Subsequently, we have studied 7 cases, 2 proved to have infants with icterus, and 5 with hydrops The edema of the scalp, or so called "halo," as reported by Hellman and Irving in 938, was seen in only 2 hydrops cases (see Fig 10a) However, these and other cases showed a Buddha or frog-like habitus of the child which may be attributed to the enlarged fetal abdomen and hydrothorax (Fig 10b) The roentgenogram in another case revealed a very large placenta The large placenta together with fetal movements within the uterus makes roentgenological demonstration of the "halo" and fetal habitus rather difficult We have come to place greater reliance on the Buddha position and recommend anteroposterior and lateral plates to show the posture of the child in suspected hydrops cases Antepartum diagnosis may be facilitated by maternal and paternal blood studies for the Rh factor if the results are interpreted with the history and clinical data presented

PATERNAL STUDIES

In a recent report, Otto stated that 5 cows serviced by the same bull had 5 hydropic calves When sired by a different bull, the same cows delivered normal calves With this information in mind, 6 fathers of infants with erythroblastosis (4 hydrops and 2 icterus) were studied The semen examination revealed a total average volume of 3.7 cubic centimeters with an average of 88 per cent normal sperm, which compares favorably with the values for healthy males as stated by Cary, who made these studies The genitalia were not abnormal One father had a cleft palate The Wassermann reaction was negative in all Complete blood studies were entirely normal except for a slight deviation from normal in the differential count These fathers were Rh positive, with 1 exception

From the evidence at hand, and since sterility is not a factor, it must be concluded that the male is not directly responsible Artificial insemination or remarriage may shed light on the subject, except that we have had 4 women with previous erythroblastosis bring forth 4 healthy infants without changing their mates

ANTEPARTUM AND INTRAPARTUM TREATMENT

Intrauterine diagnosis of erythroblastosis is important so that proper therapy can be insti-

tuted in order to prevent the condition The marked diminution of congenital syphilis following antiluetic therapy is an example of what can be accomplished by specific antepartum medication It is hoped that specific therapy will be discovered for erythroblastosis We have employed in turn a high protein, high vitamin diet, iodine, and iron, vitamin B₁, Brewer's yeast, calcium and injections of liver, vitamin B complex, 'copperin A' and calcium, without affecting the outcome Bonney and Morton used potassium chlorate, calcium, and wheat germ antenatally, but the infant had erythroblastosis From this evidence, it appears that a well balanced dietary regimen does not prevent the development of the disease in the unborn child

The evaluation of any antepartum therapy is difficult since we have had 4 mothers give birth to normal infants following a previous child with erythroblastosis without special treatment We have treated 3 mothers with frequent injections of synthetic vitamin K (thyloquinone) during the antenatal period, they having had previous infants with erythroblastosis, and each delivered a child with the icterus type of the disease, one of which died

Antepartum transfusions have been considered on the basis that if they are of benefit to the child after delivery, they may be of value before delivery We have had no experience with this procedure

The induction of premature labor has been advocated by Diamond in order to remove the child from its pernicious environment, and also so that transfusions can be given promptly We do not agree with this procedure because there is no adequate method for inducing labor without added risk to the infant Furthermore, prematurity in an infant with erythroblastosis is undesirable, for the hydrops infants are often a month or more before term, and they have a mortality rate of 100 per cent, while the icterus gravis infants are at or near term and have a lower rate of 54 per cent

Dystocia during the delivery may occur due to the ascites or to difficulty with the shoulders especially when the infant is unduly large Delivery in Case 4 resulted in a broad ligament laceration because of shoulder dystocia

Infants delivered by cesarean section have been reported in the literature by Bonney and Morton, A. F. Abt, and Pallos with the delivery of hydropic or icteric infants. This procedure is condemned except when maternal indications justify it, and should never be performed in order to improve the chances for the baby because of the high fetal mortality. We performed the operation on two occasions each time for a definite maternal indication.

Asphyxia within the uterus and asphyxia neonatorum were frequent and resuscitative measures immediately after delivery were often necessary. Therefore the use of analgesia and anesthesia during labor and for delivery should be avoided. If necessary an epizotomy can be performed, local infiltration with novocain being used. The dyspnea and cyanosis seen after delivery is further evidence of faulty oxygenation due to anemia, hydrothorax and ascites.

Therapeutic abortion was never performed in mothers with previous erythroblastic infants, on that indication alone. However it was a contributing factor in Case 5. However with the recurrence at 50 per cent for mothers who developed erythroblastosis in previous pregnancies and nearly 100 per cent when the first born is affected, erythroblastosis should receive attention from this point of view. In certain instances contraception and adoption of a child may be desirable.

Artificial insemination is frowned upon because of the increasing incidence of erythroblastosis once it has appeared and because paternal investigation has revealed no abnormality. Furthermore in Hilgenberg's case a mother had several normal children by her first husband and after remarriage had babies with icterus gravis. In Smith's case, a man with a normal child by his first wife had children with icterus gravis by a second wife. However artificial insemination with donor and recipient of the same blood group and Rh negative seems to merit investigation.

PATHOGENESIS OF ERYTHROBLASTOSIS

Many investigators, including Parsons, Hawksley and Gittins are of the opinion that hemolysis is the precursor of the erythroblastemia, and that erythroblastosis is of sec-

ondary development. Abt, von Gierke, Salmonsen and Clifford and Hertig regard the erythroblastosis as primary and a persistence of the embryonic type of blood formation. In fact, Abt states that any theory must begin by explaining the hematopoiesis. Josephs doubts that erythroblastosis is primarily a disease of blood formation since the blood returns rapidly to normal in the first 3 weeks of life. The erythroblastemia and erythroblastosis are probably secondary phenomena, since they exist in other conditions such as congenital syphilis, sepsis neonatorum, and even in premature infants as well as in infants without hydrothorax, icterus, anemia, or hemorrhagic diathesis.

It is futile to argue as to whether hematopoiesis and red cell hemolysis are primary or secondary characteristics both are present. Diamond, Blackfan and Baty regard erythroblastosis as a metabolic disturbance of the hematopoietic system. Darrow concludes that an antigen-antibody reaction explains the pathological processes, i.e. the abnormal red cell destruction, the erythropoiesis, and the hepatic injury and dysfunction. She believes that the placenta transmits the agent from the mother to the fetus. Levine and co-workers reverse the mode of transmission and theorize that when an Rh negative mother becomes pregnant by an Rh positive father, isoimmunization of the mother takes place. Hemolysis may then be initiated in the fetus by the passage of anti Rh agglutinins through the placenta. This theory is very attractive and merits much more investigation which is in progress at the present time.

The disease may begin as a dysfunction of the liver. What is the evidence to justify this point of view? The hydrops and icteric infants showed histological evidence of liver impairment as indicated by the varying degrees of hematopoiesis, deposits of intracellular pigment, and actual degeneration and necrosis of the hepatic cells. Too much emphasis cannot be given the latter findings because of postmortem changes. There was also physiological evidence of liver insufficiency since the infants showed hypoproteinemia, hypoprothrombinemia, a high icterus index and a macrocytic anemia. The patent ductus venosus must also be considered. Finally, the

anlage defect which has been postulated for the hematopoietic system can be applied to the liver, for when the child recovers, the hematopoietic system is normal, but there is evidence of residual liver damage. The high incidence of congenital anomalies in our cases makes anlage defect very plausible.

What happens? The liver fails to produce an adequate amount of serum proteins and prothrombin. In some instances this is severe enough to result in universal edema. The capillary endothelium becomes impaired and multiple petechiae, ecchymoses, and hemorrhagic diathesis occur. There is no apparent lack of antianemic principle judging from the hyperplastic state of the bone marrow. However, anemia develops probably because of excessive red cell hemolysis, and is probably initiated by the passage of anti-Rh agglutinins from the mother to the fetus. This goes on for a long time before birth as indicated by the large amounts of pigment deposited in the liver and other organs. This may also represent a failure of the diseased liver to metabolize the bilirubin, and the icterus index rises. Hyperbilirubinemia is also found in normal newborn infants either with or without physiological jaundice according to Waugh and his co-workers. Most authorities regard hyperbilirubinemia as of hematogenous and hepatogenous origin. In erythroblastosis both mechanisms form a vicious cycle and the damaged liver cannot care for the increased amounts of bilirubin, and it may pass into the maternal circulation and elevate the icterus index of the mothers as was frequently observed. When the infant is placed on its own resources after the umbilical cord is ligated, the icterus index of the infants with icterus gravis rose from 86 to 100 units and in subsequent days increased even further to 150 to 400 units. Anemia develops either within the uterus or after delivery. The diseased liver evidently cannot store adequate amounts of antianemic principle as Kracke and Garver state that it normally does. The physiological and pathological changes were invariably most marked in the hydrops infants having a fetal mortality of 100 per cent and were much less pronounced in the icterus infants, which probably accounts for the better survival rate in these infants.

The views of the older investigators that maternal nephritis and cirrhosis of the liver caused fetal hydrops again bear scrutiny. The increased incidence of pre-eclampsia and eclampsia with liver changes in the mothers and definite evidence of liver impairment in their infants with erythroblastosis suggests a common etiology for both. Pregnancy is necessary for the development of toxemia as well as for erythroblastosis. Parsons, Hawksley and Gittins, and de Lange and Arntzenius believe that a toxic agent is responsible for both conditions. Is it possible that the anti-Rh agglutinin of Levine, Katzin, and Burnham is the agent initiating erythroblastosis and toxemia of pregnancy?

CONCLUSIONS

- 1 A classification of erythroblastosis dividing the cases into hydrops, icterus, anemia, hemorrhagic diathesis, and *unclassified* types is presented.
- 2 The total incidence of erythroblastosis was 1/438. The total fetal mortality caused by the disease was 3.2 per cent.
- 3 Multiparity was an associated factor in 92 per cent of the mothers.
- 4 A high incidence of pre-eclamptic type of toxemia was found in the mothers of hydrops cases, and to a less extent in the icterus cases.
- 5 The excessive uterine enlargement, out of proportion to the duration of pregnancy, was shown to be due to the combined weight of the infant and placenta, and not to the "hydramnios."
- 6 The hydrops infants were born a month or more prematurely, whereas the icterus infants were nearer term.
- 7 Asphyxia, either within the uterus or after birth, or during the neonatal life, was a prominent symptom in the fetus. For this reason, if erythroblastosis is suspected before delivery, all analgesia and anesthesia is indicated. Local infiltration can be used for an episiotomy.
- 8 The incidence of postpartum hemorrhage was increased, particularly in the hydrops group.
- 9 The incidence of operative delivery was 56 per cent, the chief indication was fetal distress.

Infants delivered by cesarean section have been reported in the literature by Bonney and Morton A. F. Abt, and Pallos with the delivery of hydrotic or icteric infants. This procedure is condemned except when maternal indications justify it, and should never be performed in order to improve the chances for the baby because of the high fetal mortality. We performed the operation on two occasions, each time for a definite maternal indication.

Asphyxia within the uterus and asphyxia neonatorum were frequent and resuscitative measures immediately after delivery were often necessary. Therefore the use of analgesia and anesthesia during labor and for delivery should be avoided. If necessary an episiotomy can be performed, local infiltration with novocain being used. The dyspnea and cyanosis seen after delivery is further evidence of faulty oxygenation due to anemia, hydrothorax, and ascites.

Therapeutic abortion was never performed in mothers with previous erythroblastotic infants, on that indication alone. However it was a contributing factor in Case 5. However with the recurrence at 50 per cent for mothers who developed erythroblastosis in previous pregnancies and nearly 100 per cent when the first born is affected erythroblastosis should receive attention from this point of view. In certain instances, contraception and adoption of a child may be desirable.

Artificial insemination is frowned upon because of the increasing incidence of erythroblastosis once it has appeared, and because paternal investigation has revealed no abnormality. Furthermore in Hilgenberg's case, a mother had several normal children by her first husband and after remarriage had babies with icterus gravis. In Smith's case a man with a normal child by his first wife had children with icterus gravis by a second wife. However artificial insemination with donor and recipient of the same blood group and Rh negative seems to merit investigation.

PATHOGENESIS OF ERYTHROBLASTOSIS

Many investigators, including Parsons, Hawksley and Gittins are of the opinion that hemolysis is the precursor of the erythroblastemia and that erythroblastosis is of sec-

ondary development. Abt, von Guericke, Salomonsen and Clifford and Hertag regard the erythroblastosis as primary and a persistence of the embryonic type of blood formation. In fact Abt states that any theory must begin by explaining the hematopoiesis. Josephs doubts that erythroblastosis is primarily a disease of blood formation, since the blood returns rapidly to normal in the first 3 weeks of life. The erythroblastemia and erythroblastosis are probably secondary phenomena, since they exist in other conditions such as congenital syphilis, sepsis neonatorum, and even in premature infants, as well as in infants without hydrops, icterus, anemia, or hemorrhagic diathesis.

It is futile to argue as to whether hematopoiesis and red cell hemolysis are primary or secondary characteristics both are present. Diamond, Blackfan and Baty regard erythroblastosis as a metabolic disturbance of the hematopoietic system. Darrow concludes that an antigen-antibody reaction explains the pathological processes, i.e. the abnormal red cell destruction, the erythropoiesis and the hepatic injury and dysfunction. She believes that the placenta transmits the agent from the mother to the fetus. Levine and co-workers reverse the mode of transmission and theorize that when an Rh negative mother becomes pregnant by an Rh positive father isoimmunization of the mother takes place. Hemolysis may then be initiated in the fetus by the passage of anti Rh agglutinins through the placenta. This theory is very attractive and merits much more investigation which is in progress at the present time.

The disease may begin as a dysfunction of the liver. What is the evidence to justify this point of view? The hydrops and icterus infants showed histological evidence of liver impairment as indicated by the varying degrees of hematopoiesis, deposits of intracellular pigment, and actual degeneration and necrosis of the hepatic cells. Too much emphasis cannot be given the latter findings because of postmortem changes. There was also physiological evidence of liver insufficiency since the infants showed hypoproteinemia, hypoprothrombinemia, a high icterus index, and a macrocytic anemia. The patent ductus venosus must also be considered. Finally the

anlage defect which has been postulated for the hematopoietic system can be applied to the liver, for when the child recovers, the hematopoietic system is normal, but there is evidence of residual liver damage. The high incidence of congenital anomalies in our cases makes anlage defect very plausible.

What happens? The liver fails to produce an adequate amount of serum proteins and prothrombin. In some instances this is severe enough to result in universal edema. The capillary endothelium becomes impaired and multiple petechiae, ecchymoses, and hemorrhagic diathesis occur. There is no apparent lack of antianemic principle judging from the hyperplastic state of the bone marrow. However, anemia develops probably because of excessive red cell hemolysis, and is probably initiated by the passage of anti-Rh agglutinins from the mother to the fetus. This goes on for a long time before birth as indicated by the large amounts of pigment deposited in the liver and other organs. This may also represent a failure of the diseased liver to metabolize the bilirubin, and the icterus index rises. Hyperbilirubinemia is also found in normal newborn infants either with or without physiological jaundice according to Waugh and his co-workers. Most authorities regard hyperbilirubinemia as of hematogenous and hepatogenous origin. In erythroblastosis both mechanisms form a vicious cycle and the damaged liver cannot care for the increased amounts of bilirubin, and it may pass into the maternal circulation and elevate the icterus index of the mothers as was frequently observed. When the infant is placed on its own resources after the umbilical cord is ligated, the icterus index of the infants with icterus gravis rose from 86 to 100 units and in subsequent days increased even further to 150 to 400 units. Anemia develops either within the uterus or after delivery. The diseased liver evidently cannot store adequate amounts of antianemia principle as Kracke and Garver state that it normally does. The physiological and pathological changes were invariably most marked in the hydrops infants having a fetal mortality of 100 per cent and were much less pronounced in the icterus infants, which probably accounts for the better survival rate in these infants.

The views of the older investigators that maternal nephritis and cirrhosis of the liver caused fetal hydrops again bear scrutiny. The increased incidence of pre-eclampsia and eclampsia with liver changes in the mothers and definite evidence of liver impairment in their infants with erythroblastosis suggests a common etiology for both. Pregnancy is necessary for the development of toxemia as well as for erythroblastosis. Parsons, Hawksley and Gittins, and de Lange and Arntzenius believe that a toxic agent is responsible for both conditions. Is it possible that the anti-Rh agglutinin of Levine, Katzin, and Burnham is the agent initiating erythroblastosis and toxemia of pregnancy?

CONCLUSIONS

- 1 A classification of erythroblastosis dividing the cases into hydrops, icterus, anemia, hemorrhagic diathesis, and *unclassified* types is presented.
- 2 The total incidence of erythroblastosis was 1.438. The total fetal mortality caused by the disease was 3.2 per cent.
- 3 Multiparity was an associated factor in 92 per cent of the mothers.
- 4 A high incidence of pre-eclamptic type of toxemia was found in the mothers of hydrops cases, and to a less extent in the icterus cases.
- 5 The excessive uterine enlargement, out of proportion to the duration of pregnancy, was shown to be due to the combined weight of the infant and placenta, and not to the "hydramnios."
- 6 The hydrops infants were born a month or more prematurely, whereas the icterus infants were nearer term.
- 7 Asphyxia, either within the uterus or after birth, or during the neonatal life, was a prominent symptom in the fetus. For this reason, if erythroblastosis is suspected before delivery, all analgesia and anesthesia is indicated. Local infiltration can be used for an episiotomy.
- 8 The incidence of postpartum hemorrhage was increased, particularly in the hydrops group.
- 9 The incidence of operative delivery was 56 per cent, the chief indication was fetal distress.

10. When the fetus is macerated histological examination of the placenta and of the liver by means of special pigment stains offers a good opportunity for diagnosis.

11. The obstetrical history of the patient should replace the "family history" since the disease is not familial in the strict sense.

12. The degree of parity is important in predicting a subsequent case of erythroblastosis. The incidence of erythroblastosis in pregnancies after its initial appearance is approximately 50 per cent. If the first born had the disease the incidence for subsequent infants is nearer 100 per cent.

13. Case histories of hydrops and eclampsia identical twins with erythroblastosis, erythroblastosis with hemorrhagic diathesis as the initial symptom, hydrops with survival for 11 days icterus gravis diagnosed *intra uterine* and hydrops fetalis diagnosed *intra uterine* were presented.

14. Maternal blood studies were usually normal save for an increased icterus index and uric acid probably due to maternal liver damage accompanying toxemia. The serum proteins were generally reduced. Several of the mothers were Rh negative.

15. The infants had a high incidence of congenital anomalies.

16. Autopsy often revealed some degree of liver degeneration, pigment deposits, and hematomata, which were usually most marked in hydrops cases.

17. Complete studies of cord blood are presented. The number of erythroblasts and normoblasts, as well as their ratio are important diagnostic criteria.

18. The serum proteins and the prothrombin concentration of cord blood were reduced especially in the hydrops cases while the icterus index was greatly increased, also to a greater extent in the hydrops group. These changes together with the macrocytic anemia are interpreted as physiological evidence of impaired liver function.

19. The immediate treatment of erythroblastosis is to combat asphyxia. Repeated transfusions from a compatible donor in order to provide protein, prothrombin and blood cells for the infant, are imperative.

20. The mortality for the hydrops cases was 100 per cent, for the icterus group, 54 per cent.

21. Correct antepartum diagnosis was made in 8 of 10 attempts and the important criteria were stated.

22. The Buddha like habitus of the fetus *in utero* by x ray examination, is an important diagnostic feature.

23. Paternal studies including blood and semen failed to disclose any abnormality. Several fathers were Rh positive, except in one instance.

24. The management of a patient with suspected erythroblastosis is given. Cesarean section should not be performed except for maternal indication.

25. The probable pathogenesis of erythroblastosis is presented on the basis of liver dysfunction. Anatomical and physiological evidence is given to support this view. The significance of the Rh factor was mentioned.

26. Erythroblastosis runs part of its course *in utero* and the obstetrician and pediatrician in consultation are in a strategic position for antepartum diagnosis.

27. Hematological studies of the cord blood afford a prompt and simple method of making the diagnosis at the time of the delivery so that treatment may be instituted promptly.

10. When the fetus is macerated, histological examination of the placenta and of the liver by means of special pigment stains offers a good opportunity for diagnosis.

11. The obstetrical history of the patient should replace the family history since the disease is not familial in the strict sense.

12. The degree of parity is important in predicting a subsequent case of erythroblastosis. The incidence of erythroblastosis in pregnancies after its initial appearance is approximately 50 per cent. If the first born had the disease the incidence for subsequent infants is nearer 100 per cent.

13. Case histories of hydrops and eclampsia, identical twins with erythroblastosis, erythroblastosis with hemorrhagic diathesis as the initial symptom, hydrops with survival for 11 days, icterus gravis diagnosed *intra utero* and hydrops fetalis diagnosed *intra utero* were presented.

14. Maternal blood studies were usually normal save for an increased icterus index and uric acid probably due to maternal liver damage accompanying toxemia. The serum proteins were generally reduced. Several of the mothers were Rh negative.

15. The infants had a high incidence of congenital anomalies.

16. Autopsy often revealed some degree of liver degeneration, pigment deposits, and hematopoiesis, which were usually most marked in hydrops cases.

17. Complete studies of cord blood are presented. The number of erythroblasts and normoblasts, as well as their ratio are important diagnostic criteria.

18. The serum proteins and the prothrombin concentration of cord blood were reduced especially in the hydrops cases, while the icterus index was greatly increased also to a greater extent in the hydrops group. These changes together with the macrocytic anemia are interpreted as physiological evidence of impaired liver function.

19. The immediate treatment of erythroblastosis is to combat asphyxia. Repeated transfusions from a compatible donor in order to provide protein, prothrombin and blood cells for the infant, are imperative.

20. The mortality for the hydrops cases was 100 per cent for the icterus group, 54 per cent.

21. Correct antepartum diagnosis was made in 8 of 10 attempts and the important criteria were stated.

22. The Buddha-like habitus of the fetus *in utero* by x-ray examination is an important diagnostic feature.

23. Paternal studies including blood and semen failed to disclose any abnormality. Several fathers were Rh positive except in one instance.

24. The management of a patient with suspected erythroblastosis is given. Cesarean section should not be performed except for maternal indication.

25. The probable pathogenesis of erythroblastosis is presented on the basis of liver dysfunction. Anatomical and physiological evidence is given to support this view. The significance of the Rh factor was mentioned.

26. Erythroblastosis runs part of its course *in utero* and the obstetrician and pediatrician in consultation are in a strategic position for antepartum diagnosis.

27. Hematological studies of the cord blood afford a prompt and simple method of making the diagnosis at the time of the delivery so that treatment may be instituted promptly.

TREATMENT OF FRESH TRAUMATIC AND CONTAMINATED SURGICAL WOUNDS

J DEWEY BISGARD M.D. and CHARLES P. BAKER, M.D.
Omaha, Nebraska

IN the evaluation of a method of management of fresh contaminated wounds three questions must be answered. Does the method render the wound aseptic? If not, does the method injure the tissues and thereby interfere with the normal mechanism of defense against infection and of repair? And third, the all important one. What are the clinical results of the method? In the report which follows an attempt is made to answer these questions.

We believe that there is ample experimental and clinical evidence that no method in use today renders a contaminated wound absolutely free of bacteria. As a matter of fact, surgical asepsis is never absolute and even in so called sterile operative surgery the sterility is always relative. Therefore the question as to whether a given wound remains aseptic or becomes infected and suppurates depends upon two factors the quantity and the character of the micro-organisms which remain in the tissues and the effectiveness of the defense mechanism.

We also believe that there is ample experimental and clinical evidence that the chemical bactericidal agents, which are so generally used to disinfect wounds, destroy or devitalize the tissue cells with which they come in contact and thereby seriously impede the inflammatory response and impair the effectiveness of the natural mechanism of defense.

If the bactericidal agents always rendered wounds free from bacteria, the injury inflicted upon the tissues would be of little consequence. However failing to destroy all the micro-organisms, they leave the tissues damaged and less capable of coping with the bacteria which remain viable.

Both from experimental and clinical evidence accumulated by us and from similar data reported by others, we believe that wounds can be rendered as relatively sterile by me-

chanical washing with very copious irrigations of isotonic salt solution as by the application of bactericidal agents. This method has the very important advantage that it leaves the tissues essentially uninjured to mobilize the natural defenses to deal with the microorganisms which remain.

An abundance of evidence has accumulated to establish the sulfonamides as very effective bacteriostatic agents for certain bacteria. From the experimental data reported by others and from that which follows it is apparent that sulfanilamide applied directly to the tissues causes no apparent damage to the cells and does not alter the normal course of repair of either bone or soft tissues. Actually in our animals it facilitated repair in contaminated wounds by preventing infection.

EXPERIMENTAL OBSERVATIONS

I. Tissue response to application of sulfanilamide normal salt solution and a few of the antiseptic or bactericidal preparations most commonly employed. In each of 4 rabbits 5 small transverse incisions were made into the subcutaneous tissue of the abdominal wall on each side of the midline at regularly spaced intervals. Rigidly aseptic technique was employed. One wound served as a control. One was washed vigorously with isotonic salt solution. The 8 remaining were painted thoroughly with one of the 8 agents: tincture of green soap, ether alcohol tincture of iodine sulfanilamide powder and solutions I, II and III. The unnamed solutions are the commercial preparations most widely used in the United States. The wounds were closed with adhesive tape and covered with sterile dressings.

In a second series of 8 rabbits approximately 5 minims of each of the 9 test agents was injected into the subcutaneous tissues of the abdominal wall with hypodermic needles. Points of injection were marked with India Ink.

Fig 1 a, Mild inflammatory response 12 hours after 5 minims of ether had been injected into the tissues. Note slight edema and leukocytic infiltration. b, A high power magnification of a shows swollen tissue cells with poorly staining nuclei. c, Moderate inflammatory reaction 4 hours after injection of alcohol. Note moderate edema, round cell infiltration, pale staining tissue cells and a thrombosed blood vessel. d, Gross tissue necrosis and severe inflammatory response (abscess) at the site of injection of 5 minims of the tincture of green soap. Injection made 12 hours previously.

One animal in the first series and 2 in the second were sacrificed at each of four intervals following incision or inoculation, 4, 12, and 48 hours and 5 days. Blocks of skin and subcutaneous tissue containing the sites of incision

or inoculation were excised and studied microscopically. Normal salt solution provoked essentially no more tissue damage or inflammatory response than did mere trauma as measured by the controls.

Similarly there was no evidence that sulfanilamide injured tissue cells or that it incited more than a feeble inflammatory response. All of the other agents consistently gave rise in various degree to tissue reaction to injury. Curiously ether was the least, and green soap the worst, offender. The latter produced gross tissue necrosis with abscess formation in more than half of the specimens. Antiseptics II and III also were provocative of gross necrosis and abscess formation. Although iodine and alcohol caused moderate to marked inflammatory reactions no gross evidence of necrosis was found in the specimens.

Photomicrographs of specimens illustrating degrees of tissue reaction appear in Figure 1.

II Contaminated compound fractures. In 18 rabbits segments of both radial shafts measuring approximately 0.5 centimeter were removed subperiosteally and filled with constant broth suspensions of hemolytic streptococci, hemolytic colon bacilli and Staphylococci albi. The latter two cultures were obtained originally from infected wounds of rabbits.

Four animals were used as controls and after inoculation the wounds were closed without further treatment. Two of these animals died within a few days; the 2 others developed abscesses at the operative sites in both legs which drained for many days. Only 1 of the 4 fractures developed union and this was rather meager. In 3 fractures segments of the shaft had obviously been sequestered. In the 14 remaining animals the wounds were inoculated with the cultures, closed for 10 minutes, and then re-opened and filled with the test agents and antiseptic solutions used in experiment I. Thus 2 rabbits were utilized for each antiseptic agent.

A brief summary of the results in these 14 animals follows, and illustrative roentgenograms appear in Figure 2.

Wounds lavaged with salt solution and filled with sulfanilamide powder: 4 wounds—no infection and all healed by primary intention; 4 fractures—all healed normally; the bony union.

Sulfanilamide only: 4 wounds—healed by primary intention; mildly and grossly infected; 4 fractures—in all, bone repaired normally.

Ether: 4 wounds—0 infected, grossly; 4 fractures—failed to unite and partially repaired.

4. Alcohol: 4 wounds—grossly infected (one in each rabbit); fractures—both failed to repair; 1 rabbit died after 5 days—autopsy findings of consolidated lungs.

5. Tincture of iodine: 4 wounds—2 grossly infected and superficially infected; 4 fractures—3 totally ununited and partially repaired.

6. Antiseptic I: 4 wounds—grossly infected (one in each animal); fractures, one totally ununited and one partially repaired. Rabbit died after 3 days, no definite cause of death demonstrable.

7. Antiseptic III: 4 wounds—3 grossly and 1 superficially infected; 4 fractures—4 non-unions.

8. Tincture of green soap: 4 wounds—all grossly infected; fractures—both failed to repair. One rabbit died after 1 day from diarrhea and inanition.

III Influence of the topical application of sulfanilamide upon the repair of bone and soft tissues. In 12 rabbits the radius of each leg was exposed and fractured by a transverse saw-cut. The wound of each left leg was closed to serve as a control; that of each right leg filled with powdered sulfanilamide and closed tightly. Two rabbits died and there were 2 grossly infected wounds of the control legs.

The animals were killed and the specimens recovered for x-ray and microscopic study 2, 3, 4, 5 and 6 weeks after operation.

There was no gross or microscopic evidence of any difference in the rate or character of the repair of either the soft tissues or the bone in the control as opposed to the sulfanilamidized wounds. A comparison of the progress of bone repair is shown in Figure 3.

EXPERIMENTAL RESULTS

From these studies certain deductions can be made and although these deductions alone are not necessarily clinically applicable they would seem to become so when supported by similar if not identical, clinical observations.

It is apparent that the commonly used bactericidal or antiseptic solutions did not render all wounds completely free from bacteria, and furthermore that these agents caused injury to the tissues varying from edema with minor cell death to gross necrosis of the tissues. It is also apparent that these solutions caused interference with the repair of bone, presumably the result of devitalization of the osteogenic elements. It is noteworthy that ether

Fig 2 Fractures of the radius induced by resections of 0.5 centimeter segments of the shafts. Wounds inoculated with cultures of hemolytic streptococcus and colon bacillus and Staphylococcus aureus. Roentgenograms at 6 weeks. From left to right 1, Control—Wound grossly infected, an associated osteomyelitis with sequestration followed by union with a thin bridge of new bone. 2, Tincture of green soap—Suppuration, no new bone, non union. 3, Antiseptic I—as in 2. 4, Iodine—as in 2 except proliferation of new bone. 5, Alcohol—suppuration but proliferation of new bone with some union of fragments. 6, Saline irrigation and sulfanilamide—no infection and good bony union.

caused relatively little injury to tissues and tincture of green soap severe tissue damage.

Although sulfanilamide caused some edema response in the tissues it was relatively innocuous and there was no evidence that it altered the normal course of repair of either soft tissue or bone. Key and Burford likewise found no evidence of retardation of healing of uninfected fractures and soft tissue wounds in animals as a result of local implantation of sulfanilamide.

Sulfanilamide was very effective, but not completely so, in preventing infection in wounds grossly contaminated with specifically pathogenic micro-organisms. These observations confirm those of Jensen et al., and of Key and Burford. The latter found sulfanilamide more effective than the other sulfonamides.

In the animals in which the contaminated wounds were thoroughly washed with salt solution before sulfanilamide powder was applied, infection was entirely eliminated. It is our impression that the thorough washing of the wounds with salt solution disposed of most of the bacteria and was the more important step, while sulfanilamide, as a bacteriostatic agent, contributed an additional safeguard. Furthermore, there was no evidence that either agent used singly or both used jointly caused any damage to tissues.

CLINICAL OBSERVATIONS

Irrespective of the results obtained from animal investigation the merits of a method of

Fig 3 In these animals the topical application of sulfanilamide powder (lower row) did not alter the rate and completeness of fracture repair as compared to controls (upper row).

treatment can be determined with finality only through clinical application. Therefore, in the way of final judgment a brief report of the results obtained in 25 consecutive cases with major fresh wounds follows.

In 20 of the 25 cases there was good evidence from history or by fact that soiling of the wounds had occurred either by penetration of a foreign body or by exteriorization of bone. All of these patients were treated by us within 8 hours of the time of injury and in general all received the same type of treatment. It consisted of

- 1 *Rapid preliminary treatment of shock* in all cases so afflicted. Plasma being unavailable, blood transfusions were used freely for this purpose.

- 2 After alleviation of shock an *evaluation of extent of injury* was made, including roentgenograms and detailed examinations for evidence of loss of function of individual tendons and nerves.

- 3 *Cleansing and débridement* In the compound fractures in which one of the fragments protruded through a laceration of the skin, no attempt was made to replace this fragment until it had been thoroughly cleansed. We believe that this principle should be followed whenever facilities for thorough cleansing are immediately available. A fragment which has been exteriorized is always soiled and the soft tissue bed from whence it emerged is often either totally or relatively sterile. Therefore cleansing the fragment before replacing it accomplishes the major act in preventing infection and also avoids contamination of the soft tissues. Before the exteriorized fragment was cleansed the skin for a wide area about the wound was rendered surgically clean by scrubbing it with a sterile hand brush for 3 or 4 minutes with a stream of sterile water and green soap constantly flowing over the area. The bone was then washed by gentle brushing of all surfaces with a new sterile brush, while normal salt solution (and only salt solution) was constantly poured over it. Solutions other than saline such as soap and antiseptics were used only in preparing the skin.

In those cases in which the soiled fragment had been replaced before the patient came into our hands, we exteriorized this fragment after

the skin had been cleansed and washed as described.

In either case before the fragment was replaced all parts of the wound were irrigated with large quantities of normal salt solution. It must be emphasized at this time as it will be repeatedly that these irrigations must be copious, many liters of saline being used. The wound should be retracted as necessary to expose its entire extent and all surfaces should be gently agitated with gauze while the solution is flowing over them.

The fragment was then replaced and all torn and devitalized bits of fat, muscle and fascia were excised. Because crushed skin does not heal readily and often separates the crushed and devitalized margins of the skin flaps were excised whenever feasible. The wound was then again copiously irrigated with normal salt solution, its surfaces covered with a thin layer of sulfanilamide powder and the skin closed usually without drainage.

The fractures were reduced through the open wound in some instances and after skin closure in others. It is our opinion that if these fractures have been thoroughly cleansed and prepared as here outlined they may be handled essentially as clean simple fractures. This applies to the use of metallic and other foreign material for internal fixation. Whenever indicated we have made use of internal fixation and have had no occasion to regret it.

The technique of cleansing compound fracture wounds in which there was no protruding fragment, and of all other types of wounds, differed only in respect to one important detail. This the initial step, consisted of closing the wound temporarily with Michel clips to prevent soiling it while the skin was being prepared. This not only prevented the dirty wash water from running into the wound but also permitted scrubbing across the approximated skin edges. After the skin had been rendered surgically clean the clips were removed and the wound was opened widely and irrigated and débrided. If the laceration of the skin was too small to permit adequate exposure for purposes of inspection, débridement, and irrigation, it was enlarged. Regardless of the degree of soiling severed tendons and nerves in wounds treated within 8 hours of the time of

injury were sutured immediately. This can be done with little risk of infection if the wound has been properly prepared by copious irrigations and thorough débridement and by the topical application of sulfanilamide.

4 *Prophylaxis* Tetanus antitoxin was administered routinely. Clostridium welchii and perfringens antitoxin was not used.

Routinely we gave all wounds immediately a course of x-ray therapy upon the assumption that these rays are as effective in preventing infection from Clostridium welchii and other gas forming anaerobes as they are in the treatment of established infections.

5 *All wounds of the extremities were immobilized* either in traction or by splinting or casting. If a cast had been applied a small window was immediately made to expose the wound for purposes of frequent direct inspection and palpation.

6 *All patients with major wounds were hospitalized* for at least 48 hours. During this period they were kept at complete bed rest with the injured part, if an extremity, elevated above heart level. This period of hospitalization was insisted upon to assure constant observation by trained observers. During this period a minimal fluid intake of 2,500 cubic centimeters was maintained by mouth or parenterally when the oral route was not available or adequate. Blood was given until relatively normal levels of hemoglobin and red cells had been attained. Vitamin B-complex and Vitamin C were given in therapeutic doses routinely.

This series consisted of 25 cases, 14 cases with compound fractures of the major long bones, 9 with major lacerations, and 2 with shotgun wounds received at close range. Not one patient in the entire group developed a primary infection or a subcutaneous suppurative process and in 13, or 50 per cent of the cases, the wounds healed *per primam*. Both shotgun wounds, one of the thigh and one of the flank, were left open because it was impossible to close them after the shredded wound margins had been excised. In 8 of the 14 cases with compound fractures, and in 2 of the 9 with major lacerations, there was failure of primary healing of portions of the approximated skin edges. This we attributed to tension and to devitalization of the edges of the

skin flaps as the result of the original trauma. In all but one of these cases retraction of the flaps left only superficial open surfaces which healed by granulation. One compound fracture of the tibia re-compounded when the skin flaps retracted. In only 1 case was the granulating surfaces sufficiently large to make the grafting of skin a feasible aid to more rapid epithelization. All fractures promptly united and in no case did osteomyelitis develop.

In allocating credit for the prevention of infection in these cases it is our impression that, as in the case of the experimental animals, the implanted sulfanilamide powder played a large part, but a part secondary to the thorough débridement and the profuse mechanical washing with saline. That sulfanilamide is a valuable adjunct is attested to by the reported clinical experiences of many observers among whom may be mentioned Jenson et al, Stuck et al, Key and Lembeck, Campbell and Smith, Hodgeson and McKee, Johnson and Davis, Colebrook, and Brown et al.

Although there is good evidence that it is safe to place unsterilized sulfanilamide powder in wounds we have used only sterilized powder. By a very simple method the powder can be sterilized in an autoclave and at the same time be kept dry. The powder is placed in a glass container with a narrow neck and around its mouth two sheets of waxed paper are tightly secured. Prepared in this way the powder remains unchanged and as such retains its adhesive quality for the tissues.

WAR WOUNDS

Logically, the principles of treatment outlined should be effective in fresh injuries inflicted in military combat. The application of these principles under circumstances of war presents obvious difficulties. The foremost difficulty would be the provision of an adequate supply of sterile normal salt solution for copious irrigation of wounds. It is probable that this need could be met even near the line of battle by means of large tanker trucks from which the solution could be piped directly to dressing stations. It is also probable that such tankers could be provided with means for sterilizing and replenishing the supply as used

The entire extrahepatic biliary system has a dual nerve supply parasympathetic fibers from the vagus nerve and sympathetic fibers from the splanchnic nerves. A controversy which still remains unsettled, concerns which of the two carry motor and which inhibitory impulses. More recent work suggests that motor and inhibitory fibers may be found in the same nerve (23).

This discussion of the nervous supply of the extrahepatic biliary tract has considerable practical import, for from it evolved several therapeutic and diagnostic developments. Foster in 1880, was the first to suggest a reciprocal innervation between gall bladder and sphincter of Oddi i.e., when the gall bladder contracted, the sphincter relaxed. The reader is referred to the bibliography of Ivy for the extensive literature on this particular phase of the subject.

The maximal intragall-bladder pressure does not exceed the secretory pressure of the liver thereby permitting a free flow of hepatic bile into the gall bladder which occurs during the fasting period, when the sphincter is closed. With the first meal containing a stimulus for gall-bladder contraction the sphincter relaxes and the intraductal pressure falls to a level against which the gall bladder can now easily contract and evacuate itself (9, 27) either by reflex or by the same factor which makes the sphincter open itself. The normal physiological stimulus for the evacuation of the gall bladder is the passage of gastric chyme, following ingestion of fat or protein, into the duodenum.

Whether the sphincteric action of the end of the common duct is due to a true and independent sphincter or is determined by duodenal activity alone, or is regulated by both, has provoked much debate. A great part of the difficulty can be ascribed to the problems inherent in attempting to separate the activity of two so closely approximated structures. That duodenal peristalsis plays a rôle in the flow of bile into the duodenum is a fact accepted by the majority of workers. However many have found that bile sometimes may be discharged without regard to duodenal activity. We believe our method has clarified this situation in a graphic manner.

That the flow of bile is dependent upon changes in intra-abdominal pressure incident to respiration has been thoroughly disproved (8, 15, 17) despite the insistence of some (6, 7, 20, 35).

That a discussion of the physiology of the mechanism of bile flow bears considerable practical import can be illustrated best by the development in recent years of a relatively large literature on biliary dyskinesia or "dysmynergia." Interest in this subject was aroused when surgeons could not account for the obstruction to the biliary tract with the usual pathological findings. A physiological obstruction of the sphincter of Oddi was then proposed as a possible etiological factor. The reader is referred to extensive reviews of this interesting subject (2, 17, 29).

METHODS

The method in most common use today for determining the pressure within the common bile duct goes back to Oddi in 1887. He severed the common bile duct and inserted a cannula into it, directed toward the duodenum. The cannula was attached to a mercury column and the level of the column at which drops of mercury were seen to appear at the papilla of Vater was taken as the intraductal pressure. Oddi found it to be the equivalent of 675 millimeters of water. Archibald used this method in attempting to show that bile pancreatitis must be due to a spasm of the sphincter of Oddi, but was the first to use a water manometer. He found intraductal pressures of 180 to 330 millimeters of water which rose to 800 millimeters on application of 3 per cent hydrochloric acid directly to the papilla. Mann (26) using this technique has studied the sphincteric resistance in a great variety of species. Other methods of studying the sphincteric mechanism which have been used include visual observations of the exposed papilla of anesthetized animals, comparing the effects before and after section or coagulation, transplanting the proximal part of the choledochus above the ampulla, creating external duodenal biliary fistulas, and measuring the height at which a column of fluid ceases to perfuse through the common duct. Lueth (23) in Ivy's laboratory perfected a cannula

Fig 1 Experimental procedure employed Motility of gall bladder and duodenum recorded by balloon-oil manometer systems Resistance of sphincter of Oddi to a constant perfusion with 0.9 per cent saline recorded by another oil manometer Respiration recorded by balloon placed between the liver and diaphragm, leading to a fourth oil manometer Blood pressure recorded by mercury manometer Glass cannula projecting beyond duodenal balloon for drainage of perfusion fluid entering through the sphincter of Oddi and for injecting solutions into the duodenum

with which the gradient of pressure within the common bile was determined He also recorded simultaneously duodenal activity and the rate of drop perfusion through the sphincter Konan, in Japan, used a technique similar to ours, but in his experiments, the rate of perfusion through the sphincter of Oddi does not seem to have been constant, his results were not recorded together, and he did not publish any of his records

Our own experimental procedure is illustrated in the accompanying diagram (Fig 1) Fourteen experiments were completed on nor-

mal healthy fasting dogs under light pentobarbital (nembutal) anesthesia (25 mgm per kgm body weight, intravenously) In 3 dogs supplementary ether anesthesia was required for maintenance, all of these 3 were female dogs External heat was applied and parenteral solutions were administered, if necessary

Condom balloons were inserted into the gall bladder and lowermost portion of the duodenum The cystic duct was not ligated, to prevent vascular changes within the gall bladder, and in order not to destroy reflex

Fig 3 At 1, normal saline, given intravenously, produced 50 to 100 millimeter rises in sphincteric pressure with simultaneous increase in duodenal tone and motility. At 2, 5 per cent glucose, intravenous, produced a marked depression of duodenal motility and tonus with a gradual rise in sphincteric resistance. At 3, a combination of glucose and saline, intravenous, produced similar rises in sphincteric pressure as when saline alone was given, but the duodenal response was less than with saline alone. Gall bladder tone and motility increased.

RESULTS

Normal activity The sphincter of Oddi has a regular and distinct tonus rhythm. There are 10 to 20 millimeter changes in pressure which are manifested as rather large and irregular fluctuations on a control tracing. Superimposed upon these large fluctuations are 2 to 3 millimeter oscillations. We have not been able to discern three separate types of motility as described by Higgins and Mann. The sphincter tonus is completely independent of the tonus of the gall bladder, and there is a surprising lack of correlation between duodenal and sphincter activity. We have frequently noted subtetanic contractions of the duodenum to occur during normal control periods which were not associated with any significant changes in the intraductal pressures (Fig 2). In some animals it is quite true that marked duodenal spasm was coincident with spasms of the sphincter, but even in these animals this was not invariably the rule.

The motility of the gall bladder is usually manifested as 3 to 5 millimeter changes in tonus occurring at a rhythmic rate, gall-bladder activity under normal conditions was found to be independent of the spontaneous activity of the duodenum or of the sphincter and vice versa. Marked respiratory effort produc-

ing deep excursions of the diaphragm could be immediately recognized in the gall-bladder tracing and were not confused with true alterations in gall-bladder activity. At no time was there a correlation between the state of tone of each of these three organs with blood pressure and respiratory changes.

Responses to physiological intravenous solutions The administration of 200 cubic centimeters of normal saline intravenously was always followed by a significant increase in sphincter tone averaging about 100 millimeters (18 experiments on 12 animals) usually associated with a marked increase in duodenal tone and motility (Fig 3). There was no consistent change in gall-bladder motility due to normal saline and the blood pressure showed a consistent and prolonged elevation during the administration of the solution. The use of hypertonic saline, 10 to 20 cubic centimeters of 20 per cent sodium chloride intravenously, was followed by even more marked results in the direction produced by normal saline (Figs 2 and 4). The gall bladder showed a consistent decrease in tonus in every 1 of the 20 instances in which hypertonic saline was used. These responses were more immediate and more marked than with normal saline, but less prolonged. The observations on the duodenum are in line with pre-

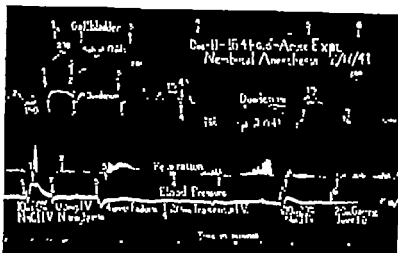

Fig. 4. The effects of drugs on spasm induced by hypertonic intravenous saline. At 2, 0.5 milligram nitroglycerin, intravenous, produced a sharp transitory drop in sphincter pressure with a slower fall in duodenal tone. At 3, 4 units of padutin had similar but more prolonged effect on the sphincter without affecting duodenal activity and in addition, produced gall bladder contraction. At 4, 30 milligrams trasentin produced a prolonged lowering of sphincter resistance 5 minutes after injection, and the following intravenous injections of hypertonic saline at 5, or of gastric juice—intraduodenal—at 6 which usually produced marked sphincter spasm were much less effective following the trasentin. Duodenal motility was practically abolished by trasentin.

vious work on the effect of normal and hypertonic solutions of saline on intestinal activity (16, 19, 31). The effects of normal saline on sphincter and duodenum were abolished by atropine in one instance and decreased by trasentin A in another. These agents have little influence on the spasm producing effect of hypertonic saline (Fig. 4). Nitroglycerine and padutin¹ produced temporary relaxation of sphincteric spasm induced by hypertonic sodium chloride (Fig. 4).

Intravenous injection of 300 cubic centimeters of 5 per cent dextrose in distilled water was given intravenously to 8 animals. Sphincter resistance increased in 3, was not influenced in 3, and decreased in 2. However in practically every instance there was a marked decrease in duodenal tone and motility. It is interesting to note that a 30 to 50 millimeter increase in sphincteric resistance occurred in spite of the decrease in duodenal activity (Fig. 3).

The intravenous injection of a 5 per cent glucose solution after intraduodenal adminis-

¹Vanadepressor was a gift of Knott and Frey.

tration of magnesium sulfate and sodium sulfate was associated with a rise in sphincteric pressure but with a continued depression of duodenal activity. Twenty to 40 cubic centimeters of a hypertonic solution of dextrose was employed in 9 dogs with effects no more marked and less prolonged than with 5 per cent dextrose. Reports are contradictory relative to the effect of intravenous dextrose on intestinal peristalsis, but our results are in agreement with the work of Ochsner et al. (11, 12). The rise in blood pressure seen was frequently greater than with normal saline.

Intravenous injection of 300 cubic centimeters of 5 per cent dextrose in 0.9 per cent saline was employed in 8 dogs with unpredictable results somewhere intermediate between the effects produced by either solution alone. The combination of those two solutions produced greater rises in blood pressure than either alone (Fig. 3).

ANALYSIS OF STUDY

The graphic evidence of the independence in the activity of the sphincter of Oddi and the

duodenum during a control period offers convincing proof in confirmation of the work of many. We have observed similar independent responses to drug stimulation. It must be clearly stated, however, that most frequently these two structures respond in an identical manner, if not at the same interval.

The effects of intravenous injection of normal saline solution on the duodeno-sphincteric mechanism was unexpected and challenging. In most experiments a prolonged and extensive rhythmic wave of contraction or spasm was produced in both the sphincter and duodenum. This is best demonstrated in Figure 1. The gall bladder did not usually react and atropine or traserutin abolished or diminished this effect of normal saline solution. This latter observation may be of importance in treatment of stones in common duct when intravenous saline has to be given.

Another physiological solution, namely 5 per cent glucose in distilled water did not affect the duodenum as did saline solution, but produced a moderate but prolonged contraction of the sphincter of Oddi, as demonstrated in Figure 3. The duodenum was relaxed following the injection of glucose.

Therefore a combination of both was tried, namely 5 per cent glucose in 0.9 per cent sodium chloride. This was followed by a slight contraction of the gall bladder, a primary depression of sphincteric and duodenal tone which would have permitted emptying of the gall bladder and which lasted for several minutes following this, waves of contraction of the sphincter and of the duodenum occurred (Fig. 3). If these experiences can be applied to man, and they may be easily tried without harm to the patient, it may be a good procedure in cases of stones impacted in the common duct, and particularly in the ampulla.

Hypertonic solutions of sodium chloride in small amounts, administered intravenously, were consistently followed by great rises of sphincteric tone, as well as of duodenal tone and contractions (Figs. 2 and 4). The gall bladder showed a small and short relaxation. Again, this observation may be of importance if it can be applied to the human. Hypertonic saline has been recommended for treatment of paralytic ileus, but in case of impacted

stone it may be contraindicated because a prolonged spasm of the duodenum and of the sphincter, together with the pressure of liver bile, may be disadvantageous in such conditions. Previous administration of a small dose of atropine or traserutin diminished this phenomenon somewhat both in power and duration, but did not abolish it.

The effects of normal and hypertonic saline solution on contractions of the sphincter and duodenum were so marked and so regular that it was possible to use this procedure for testing the effects of spasmolytic drugs on both structures.

SUMMARY

1. A method for simultaneously observing the activity of the factors most concerned with bile flow from the gall bladder has been described.

2. Sphincteric response can be independent of duodenal activity.

3. Normal or hypertonic saline administered intravenously induces prolonged periods of spastic contraction of the sphincter of Oddi and the duodenum which would constitute opposition to the flow of bile.

4. Glucose in distilled water, administered intravenously in isotonic or hypertonic concentrations, relaxes the duodenum and produces moderate contraction of the sphincter, which would offer little resistance to the flow of bile.

5. Glucose in normal saline, administered intravenously, produced an unpredictable effect, somewhat intermediate between the effect produced by either solution used alone.

6. The spasm producing effects of normal saline can be reduced or prevented by the use of atropine or traserutin intravenously, whereas these drugs are without significant effect on the spasms induced by hypertonic saline. Nitroglycerine, amyl nitrite, and padutin, given intravenously were effective in temporarily relieving the spasms produced by hypertonic saline.

CLINICAL STUDIES ON THE ANTIHEMORRHAGIC EFFECTS OF A NEW WATER-SOLUBLE VITAMIN K-LIKE SUBSTANCE

MARSHALL DAVISON, M D, FREDERICK STEIGMANN, M S, M D and
HYMEN L UDESKY, M D, Chicago, Illinois

THE discovery and isolation of vitamin K and the synthesis of substances having vitamin K-like activity constitute not only a triumph of modern chemistry but also an important advance in therapeutics. Before the discovery, only a few years ago, by Dam (8-11) of the specific fat-soluble substance called vitamin K, surgeons feared the aftermath of operations in obstructive jaundice, as obstetricians and pediatricians did the latent and active hemorrhagic diseases of the newborn, and clinicians the hemorrhagic diathesis of the cholemic state.

Dam and his coworkers are rightly credited with the discovery of vitamin K and also with postulating its economy in the animal organism. He designated the substance as the "koagulations" vitamin or vitamin K. Dam was guided to the discovery of the substance through his work on cholesterol and its possible synthesis by the hen. He had previously observed that the use of his experimental diet was followed by hemorrhages as well as by an erosive ulceration of the gizzard. The observations of Dam were soon confirmed by other workers and the literature became materially enriched and a rational basis was established for the clinical use of the substance. Almquist and Stokstad (2) were among the early workers on the problem and, simultaneous with, but independent of Dam, established the existence of vitamin K as a substance needed by the chick to maintain normal clotting time of blood.

Once the existence of vitamin K was definitely established, workers turned their attention to its isolation and synthesis. Early in 1939, Dam and his coworkers announced the isolation of vitamin K in a relatively pure form. This announcement was closely fol-

lowed by the publication of a report by Almquist and Klose (1) on the antihemorrhagic activity of synthetic 2-methyl-3-hydroxy-1, 4-naphthoquinone or phthiocol. They found that the physical and chemical properties of this compound simulated those known for vitamin K. In a letter to the editor of the *Journal of the American Chemical Society*, Binkley, MacCorquodale, Cheney, Thayer, McKee and Doisy (3) announced the preparation of the diacetates of dihydro vitamin K₁ and dihydro vitamin K₂ as further evidence that they had actually isolated both substances.

The syntheses of various quinones with vitamin K activity were announced in rapid succession. Among these was the tetra sodium salt of 2-methyl-1, 4-naphthohydroquinone diphosphoric acid ester which forms the basis for this report, and which for brevity will hereafter be referred to as preparation N-123. This substance was found by Foster, Lee and Solmssen (12) and by Almquist and Klose to possess on a molecular basis an activity much greater than that of methyl-naphthoquinone. It has been found in pharmacological studies that preparation N-123 has a wide margin of safety and adverse effects are absent in therapeutic doses.

The rationale of the clinical use of vitamin K and substances having vitamin K activity is the ability of such preparations to restore plasma prothrombin to normal levels. Vitamin K is absolutely essential for the coagulation of blood, and bile salts are necessary for the absorption of the substance from the intestinal tract. The clinical literature on the subject is rapidly expanding and published reports from various clinics are in agreement with our findings in the present study.

Butt, Snell and Osterberg (4, 5) found that the prolonged prothrombin time was reduced to within normal limits through the ad-

From the Cook County Hospital Department of Therapeutics, the Division of Surgery Northwestern University Medical School and the Department of Internal Medicine University of Illinois College of Medicine.

ministration of vitamin K and bile in their cases of obstructive jaundice. They observed that the administration of vitamin K concentrate with bile salts effectively prevented and controlled hemorrhagic diathesis, and that it made surgery in these patients less hazardous. Nygaard pointed out that transitory hypotherbinemia in the newborn may be prevented by the administration of vitamin K immediately after delivery. Scanlon and his coworkers tell of a case of obstructive jaundice in which postoperative bleeding occurred and which ceased following the administration of vitamin K. Smith and his coworkers reported that the use of vitamin K and bile salts effectively controlled postoperative bleeding in their cases. Butt, Spell and Osterberg (6) analyzed 63 cases studied at the Mayo clinic

during a period of 2 years and demonstrated the value of the preoperative use of vitamin K. Eight of the 63 cases did not receive preoperative doses of vitamin K and 5 of these patients developed postoperative bleeding.

Stewart (22) holds that dangerous hemorrhage may occur when plasma prothrombin concentration is less than 50 per cent of normal. He states that a mixture of vitamin K and bile salts will restore plasma prothrombin and control the tendency to hemorrhage. Cheney established the safety of intramuscular administration in man. Stewart and Allen observed a marked reduction in plasma prothrombin in cases of obstructive jaundice with biliary fistulas. They found a mixture of vitamin K and bile salts to give prompt improvement. Patients who did not

*48 and 72 hours after last dose

†Determination 24 hours after dose was administered

receive vitamin K before operation and who experienced severe postoperative bleeding were found without exception to have a plasma prothrombin concentration below 45 per cent Olson and Menzel reported on the use of vitamin K in 24 cases of obstructive jaundice They recommend the use of vitamin K and bile salts in all cases of jaundice, both before and after operation Rhoads and Fliegelman used a synthetic vitamin K preparation for the treatment of prothrombin deficiency in 10 patients, 9 of whom responded satisfactorily to the therapy Norcross and McFarland used a synthetic vitamin K preparation in 22 cases of hypoprothrombinaemia They found that the substance effectively controlled bleeding except in the face of severe liver damage No toxic manifestations were observed

Kugelmass pointed out that severe cases of hemorrhagic disease in the newborn may be associated with prenatal transmission of the condition This has been shown by the lowered prothrombin content of the blood of the expectant mother He cited a number of such cases in which patients were successfully treated by the administration of vitamin K Poncher and Kato had 22 cases of hemorrhagic disease of the newborn successfully treated with synthetic preparations of vitamin K, prompt cessation of bleeding occurred and in no instance were transfusions needed

CLINICAL INVESTIGATION

This report summarizes our experiences with a vitamin K-like preparation, the tetra sodium salt of 2-methyl-1, 4-naphthohydroquinone diphosphoric acid ester or prepara-

Graph 1. Typical curve as obtained in patient with obstructive jaundice but without other complications

tion N 123 in some 41 cases selected from the medical and surgical services of Cook County Hospital, Chicago. In most instances the patients represented cases of disease of the biliary tract or liver associated with jaundice. A small number of the cases studied had only gastro-intestinal disturbances or severe sepsis conducive to vitamin K deficiency.

A preliminary determination of the blood prothrombin levels according to the modified Smith method (24) was done on each patient. Then a daily dose of 10 milligrams of preparation N 123 was given over a period of 6 days. The blood prothrombin levels were determined daily for 8 days. On the seventh and eighth days, the clotting time was also determined.

METHOD OF PLASMA PROTHROMBIN DETERMINATION

Rabbit brains and lungs are used as a source of thromboplastin. They are macerated in a mortar. Normal saline solution is then added and the material is placed in the ice box where it is permitted to stand for 3 hours. The supernatant fluid is decanted and strained through gauze. Usually the solution is centri-

fuged. The thromboplastin is kept in the ice box, and it is considered advisable to warm the sample of thromboplastin to room temperature before it is used. Because of the rapid deterioration in the activity of thromboplastin, a normal prothrombin time for the sample must be determined daily.

A stop watch is used to insure accuracy in obtaining the clotting time. One-tenth thromboplastin is placed in a serological tube. To this is added 0.7 cubic centimeter of blood, drawn quickly and automatically. The time is recorded in seconds from the time the blood contacts the thromboplastin until the time the clot appears in the tube. The tube is slowly inverted until clotting occurs. A normal individual is tested several times to obtain a correct normal clotting time against which patients are checked.

Normal plasma prothrombin time in seconds
 Patient's plasma prothrombin time in seconds — per
 cent of clotting activity

Graph 3 Bizarre prothrombin level curves obtained in patients with deficient food intake and deficient absorption (pyloric obstruction, colostomy)

Graph 4 Curves showing response in prothrombin level to oral, O, and subcutaneous, S, administration of preparation N-123

A prolonged prothrombin time in seconds will give a low percentage of clotting activity. Levels below 70 per cent are to be considered dangerous, and hemorrhage may occur when such levels are reached.

Of the 41 patients in our series, 21 received a daily dose of 10 milligrams of preparation N-123, subcutaneously while 20 were given the substance per os. Of this latter group, 10 patients took the N-123 in combination with 5 grains of bile salts. The other patients did not receive any bile salts. In a small group of patients, blood prothrombin levels were determined hourly after injection of the initial 10 milligram dose. This was to determine just how rapidly the prothrombin levels rise after the patient receives the medication.

RESULTS WITH PREPARATION N-123

In most of our cases, the prothrombin level rose to normal limits within 24 to 48 hours after the initial dose of preparation N-123. After the 100 per cent level was reached and held by the daily dose, it could be maintained

for 48 to 72 hours after the medication was discontinued. Exceptions to the foregoing occurred in a number of instances, for example when aggravation of an existing jaundice or other condition caused fluctuations (up and down) in the prothrombin level even during the period of medication. Lag or fluctuation in the response to the medication occurred also in cases with sudden appearance of high fever, profuse vomiting, or starvation. In the face of existing liver damage, a definite lag in the rise of the prothrombin level was observed, and in a few cases never reached 100 per cent, also prothrombin levels could not be maintained after medication was stopped.

Patients with pyloric obstruction, or after colostomy, or with severe sepsis and the attending starvation, present a response similar to that found in cases with liver damage. Infection plus liver damage was found markedly to retard response to the therapy. In one case the prothrombin level did not rise above 80 per cent. In a number of cases of jaundice complicated by sepsis, the prothrombin levels

BACTERIEMIC STAPHYLOCOCCAL INFECTION

CHAMP LYONS, M D, Boston, Massachusetts

CULTIVATION of bacteria from the blood was first used for the study of infections due to anthrax bacilli, plague bacilli, and hemolytic streptococci. As a result of this early experience with highly invasive bacteria a positive blood culture report has been accorded undue clinical significance with connotations as to bacterial virulence and absence of host resistance. The demonstration of viable bacteria in the circulating blood is important only in relation to the kind of bacteria found and the pathological anatomy of the lesion which permitted the breaking down of the normal barrier to blood stream contamination.

A *sustained bacteriemia*, often referred to by the vague term of "septicemia," is characterized by the isolation of invasive bacteria of high virulence in relatively constant numbers per cubic centimeter of blood, a nonsuppurative cellulitis at the portal of entry and evidence of lymphatic transmission of the infection. Distinct from such blood stream infection is blood stream contamination by the *intermittent bacteriemia* of septic phlebitis or endocarditis which is characterized by a variable number of bacteria per cubic centimeter of blood, a peripheral or visceral focus of localized infection and complete absence of signs of lymphangitis. The organisms responsible for this latter type of bacteriemia need not possess any great invasive ability.

The importance of thrombophlebitis in the production of metastatic abscesses was recognized by John Hunter. Purulent phlebitis of major veins is an accepted complication of otitic and puerperal infections but septic thrombophlebitis of minor venous radicles as a cause of bacteriemia has received infrequent pathological (36) and clinical (16, 22, 32, 33, 37) consideration. In such papers it is made evident but not emphasized that the staphylococcus is the etiological organism found most

frequently in bacteriemias arising from septic thrombophlebitis of minor venous radicles.

Academic researches upon staphylococcal infection have been more definitive. The staphylococci are of limited invasiveness and cannot maintain a phase in which the organisms are resistant to phagocytosis (19). The staphylococcal exotoxins are more poisonous for animals (5, 6, 7) than for human beings (34, 35, 39, 40). Further, toxigenicity is not a criterion of invasiveness as may be recalled by tetanus and diphtheria. The tissue response to staphylococcal infection is associated with prompt lymphatic obstruction and subsequent thrombosis of the vascular capillaries (24-31). This sort of evidence has led Topley to conclude that in a bacteriemic staphylococcal infection "the cocci are carried from the original focus of infection in detached fragments of an infected thrombus."

Final acceptance of this verdict would seem to depend upon its confirmation in clinical observations. The constancy of a suppurative focus in staphylococcal bacteriemia is a surgical axiom. Occasionally the bacteriemia complicates a peripheral lesion such as a boil or a carbuncle. More frequently the local focus is in the bone, brain, kidney, or endocardium, and there is no demonstrable portal of entry. Thus there is good ground for believing that an initial bacteriemia arising from a peripheral lesion is frequently asymptomatic but permits the implantation of bacteria in vulnerable organs. The staphylococcemic phase associated with visceral abscesses must necessarily be a recurrent bacteriemia related to the active visceral focus and independent of the healed or forgotten peripheral lesion. Figures 1 to 5 present evidence of the occurrence of septic thrombophlebitis in minor vascular radicles of various viscera from patients with bacteriemic staphylococcal infection.

During the past 15 years the Massachusetts General Hospital has collected complete autopsy records upon 33 patients in whom staphylococcal bacteriemia was the primary

From the Surgical Research Laboratories of the Harvard Medical School at the Massachusetts General Hospital, Boston, Massachusetts, and the Department of Bacteriology of the Harvard Medical School.

reached normal only after about 96 hours. It is interesting to note that in some of these the prothrombin levels could be maintained for 48 hours after stopping the medication.

In our hands, cases of K-avitaminosis resulting from uncomplicated obstructive jaundice were found to respond promptly to preparation N 123 10 milligrams daily whether given parenterally or per os (Graph 1). In face of liver damage and resulting interference with vitamin K storage and utilization and in those cases with sepsis and gastrointestinal pathology (pyloric obstruction, colitis etc.) in which absorption is also impaired the response to the medication is less prompt, less complete and for a shorter period of time (Graphs 2 and 3). This observation is, of course in agreement with that of other clinicians. Naturally the degree of hypoprothrombinemia, the condition of liver parenchyma, the state of the gastrointestinal tract and the absorption mechanism (when given per os) all play a rôle in the anti-hemorrhagic effect of any preparation possessing vitamin K-like activity.

It has been our observation that when the functional integrity of the liver is not greatly disturbed impairment of vitamin K absorption as seen in certain gastrointestinal conditions and in sepsis is followed by hypoprothrombinemia only after a prolonged period of such impairment. A nearly normal prothrombin level was found in several instances of colitis, complicated peptic ulcer etc. where K-avitaminosis was suspected because of small intake of food for a long period. However in cases with liver parenchyma damage a markedly decreased prothrombin level is nearly always present. Lowest prothrombin levels are found in cases of sepsis with liver damage and sepsis with obstructive jaundice.

SUMMARY AND CONCLUSIONS

The 2-methyl-4-naphthohydroquinone diphosphoric acid ester tetra sodium salt, referred to as preparation N 123 a synthetic substance having vitamin K-like activity was used in 41 cases. Satisfactory results attended its administration. The substance has been found to be more active on a molecular basis, than methyl-naphthoquinone.

A daily dose of 10 milligrams, parenterally or per os, was found capable of raising prothrombin levels to normal within 24 to 48 hours. In many instances the normal level can be maintained for 24 to 72 hours after the medication has been stopped.

As is generally true of vitamin K preparations, the effectiveness of the substance is partially diminished in the face of liver parenchyma damage, gastrointestinal disturbances, or sepsis. The presence of any two of these factors calls for continuous administration of the preparation to maintain the prothrombin level.

Despite the fact that our patients were mostly far advanced and complicated cases, the results obtained by the use of preparation N 123 were quite satisfactory (Graph 4), even though the curves do not show such steep rise as seen in the uncomplicated cases (Graph 1).

BACTERIEMIC STAPHYLOCOCCAL INFECTION

CHAMP LYONS, M D , Boston, Massachusetts

CULTIVATION of bacteria from the blood was first used for the study of infections due to anthrax bacilli, plague bacilli, and hemolytic streptococci. As a result of this early experience with highly invasive bacteria a positive blood culture report has been accorded undue clinical significance with connotations as to bacterial virulence and absence of host resistance. The demonstration of viable bacteria in the circulating blood is important only in relation to the kind of bacteria found and the pathological anatomy of the lesion which permitted the breaking down of the normal barrier to blood stream contamination.

A *sustained bacteremia*, often referred to by the vague term of "septicemia," is characterized by the isolation of invasive bacteria of high virulence in relatively constant numbers per cubic centimeter of blood, a nonsuppurative cellulitis at the portal of entry and evidence of lymphatic transmission of the infection. Distinct from such blood stream infection is blood stream contamination by the *intermittent bacteremia* of septic phlebitis or endocarditis which is characterized by a variable number of bacteria per cubic centimeter of blood, a peripheral or visceral focus of localized infection and complete absence of signs of lymphangitis. The organisms responsible for this latter type of bacteremia need not possess any great invasive ability.

The importance of thrombophlebitis in the production of metastatic abscesses was recognized by John Hunter. Purulent phlebitis of major veins is an accepted complication of otitic and puerperal infections but septic thrombophlebitis of minor venous radicles as a cause of bacteremia has received infrequent pathological (36) and clinical (16, 22, 32, 33, 37) consideration. In such papers it is made evident but not emphasized that the staphylococcus is the etiological organism found most

frequently in bacteremias arising from septic thrombophlebitis of minor venous radicles.

Academic researches upon staphylococcal infection have been more definitive. The staphylococci are of limited invasiveness and cannot maintain a phase in which the organisms are resistant to phagocytosis (19). The staphylococcal exotoxins are more poisonous for animals (5, 6, 7) than for human beings (34, 35, 39, 40). Further, toxigenicity is not a criterion of invasiveness as may be recalled by tetanus and diphtheria. The tissue response to staphylococcal infection is associated with prompt lymphatic obstruction and subsequent thrombosis of the vascular capillaries (24-31). This sort of evidence has led Topley to conclude that in a bacteriemic staphylococcal infection "the cocci are carried from the original focus of infection in detached fragments of an infected thrombus."

Final acceptance of this verdict would seem to depend upon its confirmation in clinical observations. The constancy of a suppurative focus in staphylococcal bacteremia is a surgical axiom. Occasionally the bacteremia complicates a peripheral lesion such as a boil or a carbuncle. More frequently the local focus is in the bone, brain, kidney, or endocardium, and there is no demonstrable portal of entry. Thus there is good ground for believing that an initial bacteremia arising from a peripheral lesion is frequently asymptomatic but permits the implantation of bacteria in vulnerable organs. The staphylococcemic phase associated with visceral abscesses must necessarily be a recurrent bacteremia related to the active visceral focus and independent of the healed or forgotten peripheral lesion. Figures 1 to 5 present evidence of the occurrence of septic thrombophlebitis in minor vascular radicles of various viscera from patients with bacteriemic staphylococcal infection.

During the past 15 years the Massachusetts General Hospital has collected complete autopsy records upon 33 patients in whom staphylococcal bacteremia was the primary

From the Surgical Research Laboratories of the Harvard Medical School at the Massachusetts General Hospital, Boston, Massachusetts and the Department of Bacteriology of the Harvard Medical School.

Fig. 2. Pathology No. 70. Kidney abscess with blood vessel occluded by septic thrombus.

cause of death. The material has been analyzed in Table I. The first group contains the instances of suppurative phlebitis of major venous pathways. Deaths occurred as the result of direct extension of the thrombus to vital venous channels or as the result of massive pulmonary infarction. It is noteworthy that multiple visceral abscesses did not occur and that the lesions were confined to the involved veins and the lungs. The second group contains the instances of endocarditis. The classical pattern of peripheral and visceral infarction occurred with left endocarditis. Deaths from right endocarditis were attributable to the massive pulmonary infarction necessarily incident to such a lesion. The third group had in common one or more foci of abscess formation in the lungs and a pattern of peripheral and visceral infarction and supuration which was entirely comparable to that seen as a result of left endocarditis. Death was not attributable to the lung lesions but rather to the peripheral and visceral metastases propagated from the pulmonary thrombophlebitis incident to supuration of the septic lung infarcts. Myocardial abscesses occurred predominantly in this group. There were 2 cases with true petechiae and 4 instances of sterile visceral infarction. The fourth and last group of patients includes those with brain abscess and requires no discussion as to cause of death. It does not appear necessary to presuppose a retrograde contamination of the vertebral venous plexus from the caval system (2) to explain these abscesses.

Table II records the incidence of septic metastases to vital organs. Abscesses of the myocardium deserve special comment. Abscesses of the subendocardial portion of the myocardium may be followed by septic mural thrombi whereas abscesses of the myocardial periphery may be followed by pericarditis. Rupture of the heart through such an abscess is a recognized complication of the drainage of a staphylococcal pericarditis.

Table III summarizes the presumptive portals of entry in the reported cases. Abscesses or carbuncles, sinusitis, and prostatic infection were the chief known initial lesions. The incidence of prostatic infections is a reflection of the vulnerability to thrombophlebitis of the prostatic venous plexus. In the diagnosis of primary staphylococcal pneumonia it is important to remember that a septic pulmonary infarct may simulate pneumonia and still be the first clinical symptom of a visceral abscess.

The importance of pulmonary thrombophlebitis in staphylococcal bacteremia is emphasized in the following case report.

An adolescent girl (Case No. 228574, 7 years of age) entered with an acute osteomyelitis of the upper end of the tibia and a sustained temperature of 5 degrees F by rectum. Incision and drainage of the subperiosteal abscess was followed by intensification of her symptoms, pain in the chest, and pleural friction rub. A femoral vein ligation was performed in the hope of preventing further pulmonary infarction. Coincidental cultures of blood from the femoral and antecubital veins failed to show conclusive evidence of a more intense contamination of the blood from the osteomyelitic focus.

Fig 3 Pathology No 6208 Septic thrombophlebitis in the lung

Fig 4 Pathology No 7010 Beginning organization of a septic thrombosis of a vessel in the lung

There were no demonstrable emboli in the smear of the femoral blood. As is shown in Table IV there was a prompt reduction in the number of colonies of staphylococci in the peripheral blood after ligation of the femoral vein, and this was correlated with clinical improvement and a reduction of temperature. Four days after ligation of the femoral vein the temperature rose again, the patient became more severely ill and an intensification of the bacteremia was noted. This was correlated with a more definite friction rub, râles, purulent sputum containing staphylococci, and an increase in the respiratory rate to 40 per minute. Portable x-ray films were not completely satisfactory but failed to show a recognizable abnormality. The intensity of the bacteremia gradually diminished as the pulmonary signs and symptoms subsided. Urine cultures were consistently negative for staphylococci. The subsequent convalescence was uneventful except for a sequestrectomy, and the patient has failed to show any new foci during the 10 months since discharge. In retrospect it is felt that this patient entered with a bacteremia incident to her osteomyelitis. This was arrested by femoral vein ligation after septic lung infarcts had occurred. A recurrent bacteremia was associated with suppuration of the pulmonary infarcts as evidenced by pus in the sputum. It is important that these lung abscesses healed spontaneously.

Examination of this material has convinced me that staphylococcemia is dependent upon an intravascular focus of infection. It follows that every effort should be made in the management of staphylococcal abscesses to define the diagnostic features of septic thrombophlebitis in the stage before significant metastasis occurs. It is my clinical impression that a total white blood cell count of 15,000 or over is strongly suggestive of intravascular sepsis. Positive evidence of septic thrombophlebitis is given by a chill, a sudden spike of fever to

103 degrees F or more, a pulmonary infarct, a positive blood culture, or a palpably thrombosed vein. Septic pulmonary infarcts may simulate pneumonic consolidation so closely that it is a common clinical error to label such lesions as "bacteriemic staphylococcal pneumonia." Such "pneumonias" are often the first clinical symptom of a peripheral visceral abscess, particularly vertebral osteomyelitis, or right sided endocarditis. This latter diagnosis has been made clinically by the demonstration of multiple pulmonary infarcts in bacteriemic patients with no demonstrable peripheral or visceral focus of infection.

Scott (37) has expressed the opinion that the surgical drainage of pus under pressure is the procedure of choice in treatment of the infected vascular bed. This is sound doctrine.

but does not always prove effective. Persistent leucocytosis, fever, chills or positive blood cultures have occasionally led me to excise the inflammatory focus with subsequent prompt control of the infection.

Neuhof (32, 33) and Meleney (22, 23) are advocates of ligation or excision of veins to control purulent phlebitis in a surgically accessible vein. Obviously this method cannot be applied to intracranial venous sinuses or pulmonary veins.

The intravenous injection of immune sera has appealed to many clinicians. Blair has recently completely reviewed the problem of staphylococcal pathogenicity and immunity. On the basis of factual experimental data complicated by clinical impressionism it would appear that "within a definitely circumscribed area the injurious action of the coed and their products may be intense and this capacity far outweighs any ability to produce toxin. Antitoxic immunity may prolong life in animals susceptible to the toxin but such immunity does not afford complete protection to infection. The existence of an antibacterial immunity has never been proved and I have been unable to correlate the presence of agglutinins with eventual recovery (Table V) although Valentine and Butler (40) thought that blood stream clearance of bacteria occurred more rapidly in the presence of such agglutinins. Undoubtedly many staphylococci are destroyed in patients that survive a staphylococcal bacteremia. The nonspecific bactericidal ability of cells in the lungs, liver and spleen should not be forgotten as a part of the normal clearance mechanism.

Table VI summarizes the mortality statistics for untreated and variously treated staphylococcemic infections. Such data are almost worthless because they are based upon the entirely false assumption that staphylococcal bacteremia is a disease entity within itself. A reduction of the mortality rate from 75 per cent to 30 per cent may be statistically significant but it is far from the ideal mortality rate that might be anticipated with a specific antibacterial agent. It is significant that the intravenous injection of any of several foreign chemical substances appears to be effective in lowering the mortality rate. Meleney's (22) bacteriophage is prepared in a yeast extract broth and yeast nucleic acid is known to increase the nonspecific resistance to staphylococcal infection (3, 13). The bar

den of proof is quite clearly upon Meleney to exclude this nonspecific factor in view of the overwhelmingly adverse evidence afforded by animal experiments on bacteriophage therapy.

The importance of a nonspecific enhancement of resistance to staphylococcal infection is well illustrated by the experiments of Cowan in which active immunization with staphylococci or with a totally unrelated organism, *Pasteurella pseudotuberculosis*, was equally effective in increasing the survival rate of experimentally infected rabbits. The mechanism whereby nonspecific shock reactions increase resistance to staphylococcal infection is unknown and has never been shown to be due to a specific immune body. Peptone shock in dogs is followed by a prolongation of

the clotting time of the blood which has been correlated with an increased heparin content of the plasma and a disappearance of the metachromatic granular material of the Ehrlich

mast cells of the liver (41). Such an auto-heparinization might prove beneficial to a patient with bacteriemia arising from a septic thrombophlebitis. The successful treatment of 2 cases of bacteriemic staphylococcal thrombophlebitis of the cavernous sinus has been attributed to a combination of chemotherapy and heparin (20).

ANALYSIS OF STUDY

Bacteriemic staphylococcal infection has been analyzed from clinical and autopsy material. The weight of evidence favors the hypothesis first emphasized by Adams, Welch, and Virchow that the bacteriemia arises from an intravascular focus of infection. Such foci may occur as purulent phlebitis of major veins, as septic thrombophlebitis of minor venous radicles in and around a localized suppurative lesion or as primary endocarditis. Septic pulmonary infarction with subsequent abscess formation is followed by peripheral infarctions which make it appear that septic pulmonary thrombophlebitis may be comparable to left endocarditis.

Such a conception of the source and pattern of staphylococemia has a broad implication for successful therapy. Intravascular extension of a staphylococcal infection should be suspected in the presence of a leucocytosis of 15,000 or more, a chill, a sudden spike of fever to 103 degrees F or over a pulmonary infarct a palpably thrombosed vein or a positive blood culture. A direct attack upon the inflammatory focus may be made by excision of inflammatory foci, drainage of pus or venous ligation. The recognition of the bacteriemia as a complication of a localized inflammatory process makes it unlikely that immune serum or bacteriophage can at the present time supplant surgical treatment. The clinical results of treatment with antitoxin, antibacterial antibody, and bacteriophage do not suggest that such therapy is specific and it is entirely possible that such success as has been reported may be due to a nonspecific enhancement of resistance.

CONCLUSIONS

1. Staphylococemia has been presented as arising from intravascular foci of infection.

2. Pulmonary thrombophlebitis has been considered as a factor in the perpetuation of a staphylococcal bacteriemia.

3. Metastatic abscesses follow a pattern consistent with septic infarctions.

4. Varied surgical management is important in the treatment of bacteriemic infection.

5. It is not clear that antibacterial serum, antitoxin or bacteriophage have made a specific antibacterial effect in treatment of staphylococemia.

CARCINOMA OF THE ESOPHAGUS

Torek's Operation, Recovery

OSCAR IVANISSEVICH, M D, and ROBERTO C FERRARI, M D, Buenos Aires, Argentina

ENCOURAGED by the enthusiastic and effective work of surgeons of the United States — Franz Torek, Willy Meyer, Libenthal, Eggers, Hedblom, Garlock, Adams, King, Marshall, Ochsner, DeBakey, Churchill, Alexander, Scott, Ogilvie, Whipple, and Cartell—we faced the problem of the surgical treatment of carcinoma of the esophagus, and, although we failed in our first ten attempts, we finally succeeded in working out the technique described here

Doubtless a decisive factor in the success of this technique described is the previous pneumothorax operation as originated by Arce. This technique has been employed by him and by us since 1919. It makes intrathoracic maneuvers easier not only for the operator but for the patient. We have had a large experience with this operation, especially in the treatment of tumors of the lungs and of the thoracic wall.¹

¹Ivanissevich, Eggers y Fernandez J. C., Técnica precisa para extirpar los tumores parietales del torax emergentes en la cavidad pleural. Bol y trab Soc. de ciruj de Buenos Aires 1938 22 925. Bol. inst de clin quir 1939 123 5. Rev Asoc méd argent. 1939 52 404.

In our patient, we used spinal anesthesia with metycaine. We believe that spinal and general anesthesia with cyclopropane are usually recommended for this operation.

R. G., 87,887 of the Instituto de Clínica Quirúrgica, chair of professor Arce, M. D.

Lorenzo Tarpin, aged 52 years, laborer, Argentinian, who lived in General Pico F. C. S., province of Buenos Aires, came to the institute on September 27, 1940. His illness had begun 2 months previously with manifestations of mechanical dysphagia, noticeable at first in efforts to swallow solid foods. The first symptom he noticed was the detention of a bit of meat in the upper part of the esophagus. Twenty-four hours later the bit of macerated meat was expelled by the mouth. The sensation of a foreign body then disappeared and the passage of food was partially re-established.

This episode was repeated several times, however. The arrest of the nutritious bolus in the esophagus produced pain of moderate intensity, which disappeared once the

Fig. 1. Roentgenogram showing defect at the level of the middle third of the esophagus.

Fig. 2. Photomicrograph showing basocellular epithelioma.

Fig 3 Left posterolateral thoracotomy

food was expelled. Liquids could be swallowed normally. The swallowing of solids became more and more difficult, and the patient's general condition grew considerably worse. He lost more than 50 pounds in eight to nine months.

Fig 4 (a) the soft parts between the diaphragm and peritoneal pleura is opened. (b) shows the area of the pleura that covers the aorta of the esophagus, (c) including pleura.

Fig 5 Wide costal resection.

His family and personal history was without importance. He was not an alcoholic and smoked in moderation.

The clinical examination showed no extensible evidence of illness. He was tall man, well proportioned, of long bones, and had become much thinner. The muscular masses were moderately well developed. The teeth were in very bad condition both as to hygiene and conservation. There were no cervical glands. The respiratory and circulatory apparatus were in normal condition. The abdomen was normal. The roentgenographic examination, carried out when he entered the hospital, showed characteristic kinkage of incomplete stricture at the level of the middle third of the esophagus (Fig. 1).

On September 25, 1940, performed an esophagotomy which revealed at 37 centimeters from the dental arch an obstruction which consisted of fleshy mass and which filled two thirds of the lumen of the organ. Examination of tissues removed showed mucocellular epithelioma (Dr. Niles, September 30, 1940) (Fig. 2).

The blood analysis showed red blood cells, 5,230,000; white blood cells, 8,400; hemoglobin, 10.4; grams (95 per cent); globular albumin, 9.0; volumetric index, 10; sedimentation index, 0.5; anisocytosis, slightly marked; Wassermann reaction, negative; Kahn reaction, negative; Coagulation time, 4 minutes; bleeding time, 40 seconds; 5 minutes; Polymorphonuclear neutrophils numbered 67 per cent, polymorphonuclear eosinophils, 1 per cent; lymphocytes, 5 per cent; monocytes, 7 per cent (Dr. Niles, September 3, 1940). Chemical blood analysis revealed urea, 30; glucose, 100 mg per 100 cc.

October 1, 1940, Professor Arce performed gastrostomy following his own technique.

October 7, performed the first stage of pneumothorax (Arce). Three hundred cubic centimeters of air was introduced in the left pleura, the patient remained in the operation position. The second stage of the pneumothorax was performed, 200 cubic centimeters of air was introduced in the right pleura. Patient tolerated operation without total collapse of the lungs or objects. Immediate resolution of the lung.

Fig 6 Mobilization of the infra aortic esophagus, marked by dotted line

Fig 7 Freeing esophagus from aorta and from bronchus at level of which the tumor was located by digital dissection

On October 31, 1940, with the assistance of Drs Ferrari and Lentino, I removed the carcinoma of the esophagus following our modification of Torek's technique. Goyenechea administered spinal anesthesia with 20 centigrams of metycaïne, the patient being in supine lateral left position.

Anesthesia was perfect throughout the entire thoracic stage of the operative procedure.

TECHNIQUE

An incision is made the whole length of the seventh rib and is extended behind and above, following the interscapulovertebral space. The

Fig 8 Division and ligation of the esophagus, above, and inset, invagination of the inferior stump beneath the pursestring suture made on the fundus of the stomach

Fig 9 Dissection with the index finger extends to the cervical region above the isthmus of the thyroid gland (shown by dotted line)

Fig. 7. Exteriorization of the esophagus with the tumor, by simple traction. Removal of the tumor. Dotted line in inset indicates new position of esophageal stump.

incision includes the skin and cellular subcutaneous tissue. The wide muscles of the dorsum are divided down to the costal skeleton (Fig. 3). Careful hemostasis is maintained throughout the operative procedure.

The seventh rib is removed in almost its entire length, from the posterior angle to the neighborhood of its anterior end. About 8 centimeters of the sixth and fifth ribs are excised from the posterior angle forward (Fig. 4). The soft parts of the fifth and sixth intercostal spaces are excised between ligatures. The parietal pleura is opened in its entire length following the axis of the wound (Fig. 5). An Arce retractor is used to help to maintain the thoracotomy wide open. The lung is completely collapsed. A small quantity of serous fluid is usually present in the pleural cavity.

In front of the thoracic aorta, a few centimeters above the diaphragm, the mediastinal pleura is incised (Fig. 5). This incision is extended upward to the aortic arch. The esophagus is isolated by blunt dissection, and the tumor which has become a part of the esophagus itself is recognized (Fig. 6). In this case the tumor was attached to the bronchovascular arch. All the healthy

portion of the esophagus situated underneath the tumor is isolated from the cellular tissue of the mediastinum and the tumor is separated from its peripheral attachments by blunt dissection with the end of the index finger (Fig. 7). The esophagus is sectioned about 3 centimeters from the cardia after being crushed and doubly ligated. The inferior end is buried beneath a pursestring suture which is made by using the gastric wall. The superior end is protected with a piece of gauze (Fig. 8).

Dissection of the tumor is completed at the level of the bronchovascular region. Any fibrous attachments must be excised with scissors. Bleeding produced by this dissection is slight and is spontaneously controlled.

The mediastinal pleura is incised in the supra-aortic portion as the index finger lifts a fold of it. This incision is extended to the dome of the thorax. Digital dissection of the supra-aortic portion of the esophagus is carried out. The entire organ is then passed beneath the aortic arch and exteriorized through the incision in the mediastinal pleura.

Fig. 8. Bolding of the "gargyle" to insure accommodation of esophagus and the latex rubber tube.

situated above it. The passing of the esophagus through the narrow passage situated underneath the arch is done by pulling its supra-aortic portion, and not its inferior tied end, and of course without folding it upon itself.

Once this passage is accomplished digital dissection is continued in all the upper portion of the thoracic and cervical esophagus (Fig 9). The index finger introduced through the supra-aortic incision of the mediastinal pleura makes this step in the operation very easy.

We would emphasize the fact that if the operator stands at the ventral side of the patient—a step not described previously—he is afforded better visualization of the esophagus thus facilitating dissection. Also, in this position it is always possible to use the right hand to free the esophagus from the thoracic walls.

The thorax is closed and the dissected esophagus is left with the tumor still inside (Fig 10). This closure is final. The mediastinal pleura is not sutured. The parietal pleura is sutured. The costal wound is approximated with two thick silk sutures. The muscles of the dorsum are closed with catgut. The subcutaneous cellular tissue is sutured. The skin is closed with interrupted silk sutures. While the wall is being closed, the anesthetist distends the lung progressively using

Fig 12 Photograph of the patient with apparatus in position

Fig 13 Roentgenogram of the thorax 5 months after operation. In the left side can be seen, below the clavicle, shadow of the "gargoyle" Metastasis is not evident.

high pressure in a closed circuit with the Foregger anesthetic apparatus, oxygen only being used, no anesthetic. The thorax is not fully closed until the lung can be seen completely distended, filling all the thoracic cavity. Then the thorax is closed without drainage.

The thoracic wound is covered with gauze, and the patient is placed in supine position with the head extended and turned to the right side. Local anesthesia is used. An incision is made following the anterior margin of the left sternocleidomastoid muscle. Incision includes the skin, subcutaneous cellular tissue, and cutaneous muscle. The sheath of the sternocleidomastoid muscle is opened at the level of its anterior margin. The muscle is pulled outward and the posterior leaf of the sheath is separated, thus revealing the cervical esophagus. This dissection is very easy because of the blunt dissection which already has been done via the thorax (Fig 10).

All of the thoracic esophagus is exteriorized through the cervical wound by traction in its cervical portion.

The esophagus is excised about 3 centimeters above the tumor. By blunt dissection a tunnel is built beneath the skin of the anterior aspect of the superior portion of the thorax. In the lower end of this tunnel which is almost vertical, a transverse incision 3 centimeters in length is made in the skin. The stump of the esophagus is intro-

duced through this tunnel and its terminal opening is sutured with silk to the cutaneous wound. The cervical wound is closed in two layers (Fig. 9).

During operation the patient remained in exceptional condition from both respiratory and circulatory standpoints. There was no dyspnea.

The mediastinal maneuvers produced some circulatory disturbance as evidenced by tachycardia and hypotension. Nevertheless the tachycardia did not last more than a few minutes. During the operation 500 cubic centimeters of physiological salt solution was injected intravenously.

At the end of the operation the circulatory condition of the patient was satisfactory. Pulse was 80 and 100. A blood transfusion of 500 cubic centimeters was carried out.

After operation, the patient had a rise in temperature from the first day, the temperature fluctuating between 37 and 38 degrees C. The pulse stayed between 80 and 90. Routine therapeutic measures were carried out, saline and glucose solutions were administered, cortical suprarenal extract was given in large doses. A fairly normal diet was maintained by means of the gastrostomy.

On November 4, 6 days after the operation, pleural collection was evident and as confirmed by the x-ray picture. A small thoracotomy was performed through an intercostal space to introduce a Pezzer catheter No. 30 and 750 cubic centimeters of serosanguinolent fluid was drained. Drainage was maintained. Examination of the liquid obtained showed the following: few staphylococci and Gram positive diplococci were observed, normal quantity of degenerated leucocytes and abundant normal erythrocytes were also observed.

The temperature continued to fluctuate between 37 and 38 degrees for some days more with corresponding variation in pulse. Any movement caused tachycardia which, however improved little by little. Outside of these abnormal periods the pulse stayed between 80 and 90. Under these circumstances Dr. Marcello Can-

pane, who had been of great help during the postoperative period, advised the use of arterocofine. This therapeutic measure was very effective.

The wounds of the esophagostomy and of the thoracotomy healed *per primam*. Because the sutured skin was continuously through the esophagostomy irritated the skin and it became a better means of feeding the patient. In November a connection was established, by means of a rubber tube between the upper stump of the esophagus and the gastrostomy opening. The tube worked well and the patient was able to eat in the normal way.

The rubber connection functioned well for a period of more than 30 days. It served not only to feed the patient but also to direct the saliva toward the stomach thus preventing it from going through the esophagostomy. Little by little, however, the esophagus became ulcerated little above the clasp, and subsequent cervical cellulitis was produced. Once the tube was withdrawn the cellulitis improved, but in the suprasternal region a small esophageo-cutaneous fistula persisted that did not tend to heal. It then used suction pump effect continuous suction of the fistula. The fistula closed in a few days and the skin returned to normal condition.

A pleural suppuration, caused by the silk threads which approximated the ribs, made necessary the removal of the sutures under local anesthesia.

At present, 5 months after the operation, the patient is well. He gained 3 pounds in weight and nutrition is good. The red and white blood cells are again normal.

To secure a more perfect fitting between the esophagus and the India rubber tube, on January 30, 1931, covered the esophagus with skin. Then, a formed sort of gargoyle which is introduced in the India rubber tube (Figs. 10 and 11). The feeding of the patient is satisfactory. It has not yet been decided to build a prethoracic esophagus. It is intended to do this once the usual period of recurrence has passed.

LUNG INJURY DUE TO THE DETONATION OF HIGH EXPLOSIVE

JAMES D. KING, M.D., Ph.D. and GEORGE M. CURTIS, M.D., Ph.D., F.A.C.S.,
Columbus, Ohio

TO the neutral observer this war is truly different from previous struggles, different in its conception of attack and defense, as well as in the vulnerability of the civilian population. As a result of the development of the bombing attack, attention has been directed to new problems of war injury. Numerous reports have appeared concerning the effects of detonation of high explosive. And attention has been called to the fact that many deaths occur without evident gross injury to the body, while the necropsy reveals varying degrees of trauma to the lung. Many clinical and experimental studies have been made on the differing types of injury due to "blast" and the results appear to have given rise to varying conclusions. Moreover, in recent discussion appearing in the American literature little or no attention has been directed to this form of lung injury. It is, therefore, the purpose of this paper to review critically the recent clinical and experimental studies that have been made on the effects of detonation of high explosive, particularly on the pulmonary system, and to compare them so far as possible with the "similar" forms of lung injury as observed in peacetime civilian life.

PEACETIME INJURIES OF THE LUNG

Lung injury in the intact thorax, apart from a few isolated cases, has received but little mention in the English surgical literature. Its occurrence was recognized and described as early as 1761, when Morgagni reported two postmortem findings. Richter, in 1904, and Schwartz and Dreyfus in 1907, each gave a good account and a review of the current literature, and Fischer wrote an excellent monograph in 1912.

Thoracic injuries are to a certain extent comparable with those of the abdomen and skull in that attention is devoted less to the parietal lesion than to the possibilities and extent of damage to the contained viscera (Smith, 1840,

From the Department of Research Surgery of The Ohio State University. Dr. King, Comby Fellow in Research Surgery, served as surgeon to the First Base Hospital for the Chinese Army at Shanghai during its repeated bombing and eventual capture by the Japanese in 1937 (G.M.C.).

Sellers, 1933). Many of the cases reported were the result of severe crushing violence to the chest and the diagnosis was not usually made until postmortem examination.

Physiological anatomy of the thorax. Most writers are agreed that injury to the thoracic viscera is more frequent in children and adolescents and that this is resultant to the elastic nature of the juvenile thoracic cage. It has been suggested that the lung is simply compressed between the more resilient ribs or against the vertebral column.

In a series of experiments on the thorax after removal of the contained viscera, Triepel (1902) made the interesting observation that the male thorax can withstand more lateral and the female more sagittal pressure. Kulbs (1909), in his animal experiments, found that the chest yields more to a blow from the front and, as a whole, is less capable of resistance to this injury. Compression of the thoracic cage, according to Limon and Pera (1921) causes immediate diminution in its size, primarily at the expense of the mobility of the costovertebral and costosternal joints. When the motility of these joints is insufficient, a new factor intervenes which is determined by the elastic properties of the costocartilaginous cage.

The presence of air within the lung at the time of injury was discussed by Gosselin (1845), Gross (1866), LeConte (1908) and Adams (1933). It was pointed out that sudden compression of the air within the lung causes the lung to rupture owing to the resultant instinctive closure of the glottis, together with the withholding of breathing, thus making it impossible for the pulmonary sponge to empty.

Peyrot (1907) stresses the anatomicophysiological arrangement of the pleura. The normal cohesion of the pleural surfaces holds the lung to the parietes. Thus, if the chest wall with its parietal pleura and the lung with its visceral pleura are depressed, the remainder of the lung is prevented by its natural adherence to the chest wall from following the movement. A part of the organ which is seldom stretched is thereby put under tension and tears may result.

M 881

Fig. Gross appearance of the lung after injury by contusion in peacetime civilian life. Note the scattered areas of hemorrhage.

Du Séjour (1901) agrees that the mechanism stressed by Peyrot would explain rupture if the pleura were adherent, but thinks otherwise that there is too much gliding between the pleural surfaces. In his opinion the air-filled lung is abruptly compressed at the time of trauma and escape of the air through the upper air passage is insufficient. Hence rupture results by sudden compression as one might burst an inflated paper bag. Similar opinion was expressed by Gross (1866).

Joannides and Tsoulos (1930) after experimental work on the production of mediastinal emphysema in dogs, came to the conclusion that anything which produces an increased intrapulmonary pressure such as a severe cough, the labor of childbirth, lifting of a heavy weight, etc., probably causes a mild degree of mediastinal emphysema and air embolism, which as yet we have no way of recognizing clinically.

Morbid anatomy for injuries. The morbid anatomy of the injuries varies greatly. In simple

contusion, bleeding occurs into the lung substance as Duval (1918) has shown, producing areas of contusion at the base and apex of the injured lung with blood infiltration of varying extent—simple contusion by *contre-coup*. Duval even demonstrated small tears of the visceral pleura on the opposite side.

Rupture of the alveoli with interstitial emphysema about the capillary vessels was also noted recently in the animal experiments of Adams (1933) carried out by simulating a submarine escape. Sometimes the hemorrhage is severe and may be localized to one lobe as in an instance reported by Sauerbruch (1937). It can be even more marked as in the case of Rocher and Dupéné (1927) which is typical of gross hemorrhagic infiltration of both lungs without apparent tears in the pleura. Similar observations were also reported by Duval.

Fischer (1912) gave an anatomical classification of rupture of the lung according to the severity and site of the lesion: (1) Crushing into a shapeless mass of one lobe of the lung or of the whole lung; (2) internal rupture of the lung with intact visceral pleura; (3) complete penetrating rupture of the lung; (4) separation of one lobe of the lung.

Cooke (1936) more recently presented a clinical classification of pulmonary injuries: (1) the pneumothorax type; (2) parenchymal rupture—this is a simple rupture without laceration of the visceral pleura; (3) combined types.

Tears of the larger bronchi are known to occur (Davis, 1890) and are compatible with life provided the patient survive the immediate effects of the injury (Davies 1930, Clerf 1940).

Lung injury without trauma to the thoracic cage may be produced by the following causes: (1) Run over by a heavy vehicle—accounts for 1 out of 70 cases in Fischer's series—Wason, Smith, Tatum, Johnson, Harlan, McDonnell, Ashburn, Laurent, Kerr, Meroude, Richter, LeConte, Ville gas, Sauerbruch; (2) blow on the chest—Davies, Bogdan, Spiers, Payne, Scott, Connolly, Dickenson, Head, Fallon; (3) fall from a height—Gosselin, Gross, Wharry, McTaggart; (4) lifting a child by the arms—Cockle; (5) glancing blow of a bullet—Rees; (6) increase in the intrapulmonary pressure by coughing—Stranek, Sauerbruch, during parturition—Cunnington, dyspnea during tracheotomy—Werwath, violent respiratory effort—Waters; (7) nearby explosion—Delacroix, Ravaut, Thomas, Sencert.

ILLUSTRATIVE CASE REPORT

An example of this type of injury from our own records is presented as follows:

Autopsy No 1238-1581 (Arch 1097) White boy, aged 12 years. The history relates that he was playing with two other boys at the city gravel pit. They built a cave in the side of some loose shale. The roof suddenly caved in and the boy sustained a heavy crushing blow on the chest by large pieces of falling shale and loose earth. When dug out he was found bleeding from the nose and was brought immediately to the hospital. He was pronounced dead upon reaching the hospital.

On examination blood was found in the ears, nose, and mouth. No other abnormality was found. The clinical diagnosis was fracture of the skull.

Postmortem examination revealed fracture of the base of the skull. The left lung weighed 350 grams. The pleura was unusually hemorrhagic. The lung was expanded and many small hemorrhagic spots appeared scattered over its pleural surface. On its cut surface appeared numerous areas of petechial hemorrhage. The bronchi were filled with foamy blood. The right lung presented identical changes (Fig 1).

Microscopic examination of the lungs revealed multiple areas of hemorrhage of varying size scattered throughout the entire lung. Many of the alveoli appeared disrupted and filled with red blood cells. The bronchi and bronchioles were also filled with red blood cells (Fig 2).

This is an instance of peacetime injury of the lung without evidence of external injury. It was not recognized clinically. The fact that extensive visceral damage can be produced without revealing any *external* evidence is important from many points of view. The clinical significance of this example is obvious and has been recognized by certain surgeons.

THE NATURE OF HIGH EXPLOSIVE EFFECTS

Having reviewed traumatic lung injuries without external lesion as they are encountered in peacetime civilian life, it remains to compare them with the lesions produced by the detonation of high explosive. Many have a vague knowledge of the nature of explosives. This doubtless explains their ready acceptance of fantastic stories of the discovery of explosives of extraordinary power, tales of which are so often circulated.

"Explosion" has been defined as "the act of exploding, a rapid combustion, decomposition or similar process resulting in a great and sudden development of gases, and consequent violent increase of pressure, usually causing a loud report."

"Explosive" is any substance that may cause an explosion by sudden combustion or decomposition. Two categories are recognized, low and high explosives. Low explosives are those having explosion velocities of a few thousand feet per second or less. Members of this group are characterized by a comparatively slow "push" type of explosive effect. High explosives are those having explosion velocities of from 5,000 to 25,000 feet per second and, consequently, have quite a different effect. The violence of their detonation produces an

Fig 2 Photomicrograph of the lung appearing in Figure 1. Note the hemorrhagic exudate in the ruptured alveolar spaces.

extreme shattering effect in the immediate vicinity.

"Detonation" is a violent explosion, one resulting from practically instantaneous decomposition or combustion of unstable compounds.

A "bomb" has been defined as "a hollow projectile of iron, generally spherical, containing an explosive material which is fired by concussion or by a time fuse, also any similar receptacle of any shape containing an explosive, as a dynamite bomb" (Muehlberger, 1937).

The British speak and write of the immediate effect of the detonation of a modern high explosive bomb as "blast."

The chemistry of high explosive High explosives depend for their action upon the instability of the chemical equilibrium of their constituents. They consist of compounds of carbon, oxygen, nitrogen and hydrogen so feebly combined that when fired by combustion or detonation, new, simpler and more stable gaseous compounds are formed. Once chemical action is started it proceeds with great velocity and the explosive is immediately converted into gases with the evolution of heat. These

M 881

A "bomb" has been defined as "a hollow projectile of iron, generally spherical, containing an explosive material which is fired by concussion or by a time fuse also any similar receptacle of any shape containing an explosive as a dynamite bomb" (Muehlberger, 1937)

The British speak and write of the immediate effect of the detonation of a modern high explosive bomb as "blast"

The chemistry of high explosive High explosives depend for their action upon the instability of the chemical equilibrium of their constituents They consist of compounds of carbon, oxygen, nitrogen and hydrogen so feebly combined that when fired by combustion or detonation, new, simpler and more stable gaseous compounds are formed Once chemical action is started it proceeds with great velocity and the explosive is immediately converted into gases with the evolution of heat These

gases, now occupying an enormously greater volume than the original substance have powerful disintegrating properties. High explosives are violent detonating at the rate of several miles per second, many times greater than the speed of the most violent hurricane (Blouin, 1882; Logan 939 Storm 939).

The nature of Blast. By blast or explosion is further designated the compression and subsequent suction wave which is set up by the detonation of high explosive. At every point in the immediate neighborhood there occurs first a momentary wave of high pressure (for about 0.006 seconds for a 70 pound charge) and then a negative suction pressure due to the fact that the positive compression wave has reduced the density of the air behind it to below normal atmospheric pressure. Like the pressure component, the suction component of the blast wave lasts but for a fraction of a second, yet as a rule for a longer period than the compression wave (p. to a. 3 seconds for 70 pound charge).

The wave of pressure is highest in the immediate region of the explosion and falls off rapidly as it moves away. Thus 15 feet from a 25 pound charge, the hydrostatic pressure may be of the order of 200 pounds per square inch, whereas 50 feet away the maximum pressure recorded will not be more than 10 pounds. Everything in the immediate neighborhood of the explosion of a big bomb will therefore be suddenly exposed to a violent pressure wave of many times atmospheric pressure whereas everything 50 feet away will be exposed to only two or three atmospheres of pressure.

The suction component of the blast wave is always weaker than the pressure component and in no case can it be greater than 15 pounds per square inch since this corresponds to complete vacuum. The magnitude of the pressure and suction components of a blast wave are correlated directly with the amount of explosive and are much higher for larger than for smaller amounts (Roomary 1910 Taylor 932 Zukerman 1940).

The physics of blast. The prime characteristic of any form of wave motion is that whereas the disturbance itself moves forward, the particles of the medium through which it passes do not move with it, but oscillate backward and forward about the position of equilibrium. The plane of oscillation may either cross the line of propagation, called transverse waves, or parallel the line of propagation called longitudinal waves.

For the sake of simplicity imagine that the origin of the blast is a small sphere of explosive material. When this is detonated it expands suddenly

and compresses a spherical shell of air immediately surrounding. Thus the blast wave consists of a compression followed by a rarefaction as it is propagated outward.

The maximum movement of any air particle on each side of its normal undisturbed position is called the amplitude of the wave and clearly depends upon the violence of the explosion. In the case of aerial bomb explosions such as are now being experienced in Europe, the amplitudes are considerable for in the compression part of the wave pressure up to 200 atmospheres—that is and 35 tons per square inch—have been observed.

The phrase "beating the air" is commonly used to denote ineffectiveness. Beating the air is normally ineffective because the mobility of the air generally makes it easy for it to escape around the edges of the vulnerable object. The more sudden and violent the beating the less is this true, and the more will the air act not like a mobile gas but a rigid object, so that the violence of blast can even bruise the walls of the lung as if they had been hit by a solid object (Bertolot, 1885; Barlot, 1932; Sutherland, 1940).

THE EFFECTS OF DETONATION OF HIGH EXPLOSIVES

The extraordinarily varied effects of bombing on buildings in cities and towns have been vividly described and minutely detailed by Haldane (1938) Langdon-Davies (1939) and others from their experiences in the Spanish War. They described how when bombs burst in a street, the metal shutters of the shops which had not been hit were sucked outward. When a bomb exploded inside a house, large part of the shattered walls fell inward.

According to Logan (1930) Zukerman (1940) and others, a man may be wounded by a bomb explosion either by being hit by fragments of the bomb-casing or by masonry or some other hard substance falling or sent flying by the explosion or by being violently thrown or by being affected by the blast wave without being thrown.

Lockwood (1940) and Logan reported that during World War I (1914-1918) men were sometimes picked up in the field dead from an explosion without revealing any external injury and some times with blood-stained fluid trickling from the nose or mouth. Similar experiences were described by Mogana (1938) Langdon-Davies (1939) and Mitchener and Cowell (1939) in the Spanish War.

Again, in this war there have been reports of the damaging effects of blast on domestic animals. The damage to the lungs, characterized by al-

veolar rupture and hemorrhage, has been the consistent and dominant feature

CLINICAL INVESTIGATION

Early observations The literature on this subject is limited because this form of injury was not well known prior to the last war (1914-1918). Nevertheless, the earlier clinical observations had led to the belief that the lesions and death from the explosive effect were due either to gases such as carbon monoxide produced from the detonation of the explosive (Brouardel, 1887, Cenas, 1887, Dujol, 1887, Servel, 1887, Mitchell, 1897, Urie, 1904, Bahier, 1905, Fabre, 1906, Hatton, 1911), or resultant to a sudden vacuum effect in those parts of the body which contain gas, e.g. the lung lobules, stomach, or intestine. Thus, experimentally, gas bubbles may be set free in the blood by the sudden evacuation of a chamber in which an animal is placed. These bubbles may then block the circulation as in compressed air workers or deep sea divers when they are too rapidly decompressed (Bert, 1875, Granjon-Rozet, 1877, Gaudin, 1887, Guinand, 1887, Reynaud, 1887, Thomas, 1917, Hill, 1917).

The earlier clinical observers also reported that this form of trauma produces injuries in the nervous system (Hinchliff, 1875, Coskery, 1877, Duret, 1877, Michel, 1878, Tryon, 1891, Matignon, 1907, Zangger, 1907, Querleux, 1908, Etonensis, 1909, Llewellyn, 1910, Stierlin, 1912, Claude, 1914, Laurés, 1915) and in the lung (Reynaud, 1887, Paucot, 1901, Delacroix, 1907, Ravaut, 1915, Thomas, 1915, and Sencert, 1915).

Recent observations Gatti (1918) presents a case of acute paralysis with subsequent atrophy following the explosion of a large bomb without actual contact. The condition was similar to that seen in anterior poliomyelitis and the assumption is made that the concussion injured the motor portion of the spinal cord. Similarly Cramer (1919) reports the case of a young soldier who presented the signs of a severe aortic insufficiency after being thrown several feet into the air by the explosion of a bomb. This patient had previously been healthy and had not had those diseases which might predispose to such a heart lesion.

Mott (1916, 1917) reported several patients as having died of explosive concussions in which two outstanding lesions were observed. First, the hematomas present in the lung, and second, the extreme vascular injury to the brain. He believed that the enormous aerial compression "may be transmitted to the fluid about the base of the brain and cause shock to the vital centers of the floor of the fourth ventricle, causing instantaneous

arrest of the function of the cardiac and respiratory centers." This, he held, explained many of the instances of sudden death in which no visible injuries to the body were evident. Similarly Haldane, in describing a personal experience of his own during World War I when he was in the vicinity of bursting shells, thought that death under such conditions might be due to respiratory paralysis. Other similar observations of injury to the nervous system from the effect of explosion were also reported by Chavigny (1916), McWalter (1916), D'Abuno (1916), Meige (1916), Littermitte (1917), Pachanton (1917), and Marage (1918).

Mogena (1938) saw several instances of soldiers in Spain suffering from violent "bodily commotion" from proximity to a bursting shell. Examination of those killed by explosion (without obvious external injury) may reveal a tear of the lung, or a bulbar hemorrhage in others who live for a time, rupture of meningeal vessels, hemorrhage from intestinal laceration and other internal trauma. In some the hemorrhage might not appear for 2 to 3 days. The author explains this as due, in his opinion, to gas embolism from sudden atmospheric decompression.

Falla (1940) reported a case with capillary hemorrhage in both lungs due to blast. The patient died 12 hours following operative intervention for bleeding from a laceration of the thigh after the use of open ether anesthesia (Fig. 3).

Dean and Allison (1940) observed 27 instances, and in all but two evidence of serious or gross pathological changes in the chest was absent. They called attention to the relative disproportion in frequency between the symptoms and physical signs in the cases studied, the frequency of a ballooned appearance of the chest and the radiological appearance of a diminution of rib expansion. A similar observation was made by Rose (1940).

Roberts (1940) pointed out the contraindication to surgical operation. Of two patients whose abdomens had been opened for intense abdominal symptoms, neither presented any demonstrable lesion and the thoracic injury appeared to be the real cause. He calls attention to the fact that if a group of bomb casualties contains one blast case it probably also contains others, even though the signs and symptoms are lacking.

Hadfield et al. (1940) reported 10 cases of sudden death in persons subject to the blast effect of high explosive bombs. In none of these was there any evidence of external trauma. There were gross hemorrhagic lesions in both lungs in all, and blood stained secretions in the upper air passages in

Fig. 3. Photomicrograph of the lung of a man who died as a result of injury sustained in an air raid (Fallin's case). The alveoli, which are disrupted, are filled with blood cells. (After Zakarian.)

some. Again they reported a case in which a man aged 23 lived for 51 hours after exposure to a blast. As a result of this observation they believe that patients who develop pulmonary hemorrhage without external trauma to the thoracic wall continue to bleed into the lung for a period which may amount even to 48 hours. In the light of the post mortem finding of continued bleeding they concluded that these patients should be treated as strictly as if they had had recent severe hemoptysis (Fig. 4).

O'Reilly (1941) stated that from 3 cases which he had studied one clinical point had emerged that within 48 hours in 2 and within 4 days in the other the clinical findings of an ordinary lobar pneumonia had apparently developed. Again 5 patients belonging to the same "incident" were brought in with the appearance of acute abdominal catastrophe—rigid abdomen, pain, and so on. Two were sufficiently serious to require surgical intervention, but nothing was found except a few minute subserous hemorrhages.

Ross (1941) made a comparative postmortem study of peacetime and wartime lung injuries and concluded that the main points of difference may be summarized as follows:

In compression asphyxia the lesions may be symmetrical on both sides but not necessarily. The hemorrhages are usually subpleural and in the

lines of the ribs. There is generalized pulmonary congestion.

2. In hemorrhage due to impact of a solid the hemorrhage is in relation to the point of maximum impact and may be unilateral. The lung tissue is contused, torn and filled with blood at or around this point.

3. In "hemorrhagic concussion" (due to blast) the lesions are always bilateral and roughly symmetrical. There is general congestion of the lung. Pleural hemorrhages are present only as an extension from deeper areas.

Osborn (1941) from the results of his comparative study of peace and wartime injuries to the lungs states that there are two forces which bring about the capillary hemorrhage in hemorrhagic concussion. These are compression of the lungs through the chest wall and diaphragm and the counterpressure exerted by the air in the alveoli. The actual lesion is mainly hemorrhage from the alveolar capillaries. The lesion itself is not progressive as Hadfield et al. claim, but the reaction is. Treatment is largely in the anticipation of complications.

In conclusion he states that to understand the lesions described for blast in animals and men there is no need to assume that blast has any mysterious properties. It is only a more severe diffuse sudden compression of the chest and abdomen than we see in civil cases during peacetime.

Rohb-Smith (1941) after the study of 789 consecutive accident cases of all types again called attention to the fact that the pulmonary symptoms which arise from exposure to the blast of high explosive may be due to a combination of pulmonary concussion and fat embolism, and fat emboli should be specifically looked for in autopsies on air raid casualties. A similar observation was also reported by McKibben (1939) from his experimental study.

Experimental observations. The prevailing idea formerly was that the nervous system was especially sensitive to this form of trauma. This received the support of Mott and others. However clinical and postmortem observations have now established that the pulmonary lesions predominate.

Carver and Dinsley (1919) report experiments on fish, rats, and mice. They state that the animals which were more exposed to detonation showed hemorrhages from the ears, nose, and mouth and when sacrificed exhibited varying degrees of internal hemorrhage in the viscera and central nervous system while the alveoli of the lungs were nearly always found to a certain extent ruptured.

Mairet and Durante (1919) have published several reports concerning concussion shock, the last of which presents their conclusions and opinions based upon a considerable amount of experimental work. They exposed rabbits to the detonation of high explosive under various conditions and made a particular study of the resultant lesions. The symptomatic behavior of the animals was also noted. The viscera of the animals at necropsy were found to be normal except for the lungs which were spotted with hemorrhagic areas. On the surface of the cord in all cases they found varying amounts of blood suffusion, irregularly distributed, with small clots adhering to the nerve roots. The brain appeared normal or showed petechial hemorrhages at various points on the surface. Upon these observations they developed a theory that concussion shock is due to vibrations set up in the atmosphere which, transmitted to the organism, act injuriously by violently agitating the unprotected tissues.

Hooker (1923) determined the physiological effect of air concussion. Experimental observations were made upon dogs, cats, rabbits, and frogs exposed at various distances to small charges of explosive and to gun-blast. According to this investigator, bruising with rupture of the lungs was the single gross lesion found postmortem, and this lesion was probably the primary cause of death when it occurred.

Barcroft (1940) also investigated the physiological effects of "blast" and established four points from his experiments: (1) that only animals placed in the open and within 15 feet from the exploding bomb suffered ill effects, (2) that the Anderson shelter gave immunity at 15 feet and outward to "blast" injuries, (3) that the animals situated further than 15 feet suffered no demonstrable lesion of their organs, and (4) that the lesions found in the animals nearest to the explosion were essentially in the lungs. Histologically, these lesions consisted of bruising of the lung surface along the line of the ribs and vertebral borders, and extended for one-quarter to one-half inch into the lung tissue. Other small hemorrhages were found deeper, especially around the small bronchi. From a study of animals observed over a subsequent period of weeks, the exposure to "blast" appeared to have had no permanent effect.

Until recently, the manner in which the pulmonary lesions are caused by the "blast" had not been studied. Various workers have, however, speculated about this on the basis of the character of the lesions and three possibilities have been suggested. The first is that the lesions are due to

Fig. 4. Cut surface of the lung of a girl found dead in a public shelter which received a direct hit by an aerial bomb. Note the distribution of the hemorrhages which are most extensive in the deeper parts. (After Hadfield et al.)

the lowering of alveolar pressure by the suction wave, acting through the respiratory passage with the consequent rupture of the alveolar capillaries. The second is that the lesions are caused by the distention of the lungs with air. The third is that the lung lesions are due to the impact of the pressure wave on the chest wall.

Zukerman (1940) in a recent, more elaborate investigation designed to determine the mechanism by which the lung lesions were produced, confirmed the extensive injury to the lung tissue in a wide variety of animal species. The view which his experiments substantiated was that the lesions were due to the impact on the thoracic wall of the pressure component of the blast wave. Rabbits were exposed to the explosion of hydrogen and oxygen in balloons. When very close to the bal-

Fig. 5. Moderately severe hemorrhages in the lungs of rabbit exposed to blast. (After Zukerman.)

loon the lesions were found mainly or entirely localized on the side facing the balloon. It appeared to be a direct impact effect and not some more general pressure effect through the trachea. In the latter instance the lesion would be expected to be bilateral. In another set of experiments one half of the animal was covered with sponge rubber. If the covered side were placed toward the explosion the animal sustained practically no lesions, but if the covered side were away from the explosion it received many lesions on the uncovered side facing the explosion.

Near the explosion of a 70 pound charge (133 to 18 foot distance) the animals would be found dead within one minute. At these distances the positive component of the blast wave (hydrostatic pressure) varied between 126 and 63 pounds per square inch. Further away in a zone of lower pressure (at 8 to 20 feet) the animals would die as a rule within 24 hours. The clinical features were fairly constant including air hunger and dyspnea. Still further away was one (130 to 50 feet) in which the animals survived and recovered and in which they showed no external appearance of injury, though postmortem examination revealed characteristic visceral changes.

In none of the animals which died was there any external sign of injury and in no case were fractures observed. The predominant lesion was bilateral traumatic hemorrhage in both lungs vary-

ing in degree according to the distance of the animals from the explosion (Fig. 5).

Microscopically the lesser degrees of damage appear as a small zone in which the alveoli and the smallest bronchioles are filled with blood. The alveolar walls are often disrupted, the hemorrhage originating in the torn alveolar capillaries. In severe grades of damage large areas of the lung are disrupted and hemorrhagic and the larger bronchi become filled with blood (Fig. 6).

No changes were observed in the other organs and tissues of the body. Zukerman concluded by emphasizing that in the case of fatal injuries due to blast, what actually caused death in such cases—in fact, what caused death in experimental animals subjected to blast alone was not known, and it was to the solution of that problem that some experiments at the present are being directed.

Stewart et al. (1941) more recently report their experimental investigation of blast injury to the central nervous system. Again, they emphasize that lesions of the central nervous system may be produced. They state that though pulmonary damage is apparently a constant finding and at times is very extensive it seems unlikely that it is responsible for either sudden death or later fatalities except in a contributory way. They suggest

that the mechanism responsible for the cerebral lesion was the hydraulic like pressure on the central nervous system, in its firm encasement, resulting from sudden compression of the thoracic cage with consequent violent back-pressure on the venous side.

TREATMENT OF THE INJURED

Prevention. On the basis of both the clinical and experimental observations it may be stated that prophylaxis is possible. And there are two measures of direct importance in the prevention of this form of trauma.

First is the application of the general principle of protection from the blast wave by the use of air raid shelters and the like such as ditches, holes, and gutters on the ground. As an emergency measure one should lie flat on the ground in the prone position, since the back yields less to injury than the front part of the chest.

Second is the application of some direct measure of protection by covering the chest with sponge rubber or some similar material.

Management after the injury. The importance of early recognition of the lung injury in order to treat it rationally cannot be overemphasized. If, for example, as the result of careful clinical observation it is concluded that pulmonary lesions are

present in those whose degree of shock is out of proportion to the apparent severity of the injury, then the indication will be to avoid unnecessary operative intervention and open anesthesia and to concentrate on the treatment of the shock.

It is too soon to determine in full the treatment which may be required. *Complete rest* is essential, and in view of the condition of the lungs found at necropsy and the embarrassed breathing clinically, every effort should be made to avoid any additional trauma and work that might be added to the already traumatized lungs. Oxygen therapy would consequently appear to be worthy of more extensive use. Above all, an awareness that such damage to the lungs may occur should stimulate all concerned to be watchful for this hidden type of danger among those injured in air raid casualties.

SUMMARY

This war differs from those preceding in that aerial bombing has assumed a dominant rôle in the attack. Consequently, the civilian population is, at least in certain phases of the struggle, more vulnerable to attack than the military personnel. This new technique of warfare has created other problems of injury and particularly to the lungs, however, lung injury in the intact thorax occurs more frequently during peacetime than has been formerly recognized and reported.

The pertinent physiological and morbid anatomy of the thorax is reviewed. A case of lung injury unrecognized clinically and discovered at postmortem, similar to that of the lung injury from blast is presented. A brief review of the power of high explosive, and of the nature and physics of the explosion is presented. The outstanding clinical findings of blast injury to the lungs are as follows:

Symptoms may vary from a slight degree of respiratory distress to a complete cessation of respiration depending on the degree of injury inflicted by the blast wave. In general, varying degrees of shock are present accompanied by dyspnea. Cough and hemoptysis also are frequent. Symptoms referable to abdominal and cerebrospinal nervous disturbances have been reported.

Physical examination reveals, in general, no gross injury particularly pointing to the thorax. However, one clinical aspect of importance dealing with this type of injury that demands constant attention is that the gross lesions found elsewhere in the body must not be allowed to overshadow the possible lung injury which is now known to be probable without evidence of external

Fig. 6 Photomicrograph of the lungs of a rabbit exposed to blast, showing many alveoli filled with blood cells and the disrupted alveolar walls. (After Zukerman.)

injury to the chest. The importance of this special precaution, clinically, cannot be overemphasized. The presence of blood in the nose or mouth and bloody sputum, and the characteristic x-ray appearance of the chest are of considerable diagnostic importance.

The *postmortem findings* always reveal extensive hemorrhagic lesions in the lungs. All cases show general pulmonary congestion. Pleural hemorrhages are present only as an extension from deeper areas.

The results of the experimental studies carried out by various investigators have confirmed the clinical and *postmortem* findings that pulmonary lesions predominate. The view substantiated by the recent experiments is that the lesions are due to the impact on the thoracic wall of the pressure component of the blast wave. More recent studies have again called attention to the evidence that lesions of the central nervous system may be produced by blast. It has been suggested that the mechanism which is responsible for the cerebral lesion was the hydraulic-like pressure developed from sudden compression of the thoracic cage with consequent violent back pressure on the venous side.

Prevention of this form of injury is better than treatment. Both the general and direct measures for prevention have been discussed. The principles of treatment have been discussed in the light

of the available clinical and experimental observations and attention is called to the necessity of keeping in mind this type of lung injury regardless of whether injuries are found elsewhere in the body.

CONCLUSIONS

1. Lung injury without external evidence of trauma occurs more frequently in peacetime than has been recognized and reported.

2. In a bomb explosion the pressure wave of the blast may produce pulmonary lesions without resultant evidence of injury to the thoracic cage. The lesions are principally due to the impact on the body wall of the pressure component of the blast wave. That this form of trauma produces lesions predominantly in the lung is now abundantly confirmed.

3. It appears that the mechanism responsible for the cerebral lesion is the hydraulic pressure on the central nervous system, in its firm encasement resulting from sudden compression of the thoracic cage with consequent violent back pressure on the venous side and that this mechanism may prove

to be the explanation for the cause of sudden death in certain cases reported.

4. Prevention is better than treatment; the necessity of providing adequate general and direct protection, particularly to those who are prone to exposure to the bombing attack is evident.

5. After injury complete rest is essential. Every effort should be made to avoid any additional trauma and add extra work to the already damaged lungs. Oxygen therapy should be used more extensively.

6. The knowledge that such damage to the lungs may occur should stimulate all to be watchful for this type of injury especially among our raid casualties.

7. This review by no means concludes the problem of lung injury due to the detonation of high explosives. It is hoped that present and future investigations will bring greater and more accurate knowledge.

CAUDAL ANESTHESIA

Its Use in Obstetrics

ALBERT H LAHMANN, M D , F A C S , and A C MIETUS, M D , Milwaukee Wisconsin

FOLLOWING the successful use of caudal anesthesia in proctological operative procedures at the Milwaukee County General Hospital, its adaptability to the obstetrical service was tested. A brief review of the first 400 cases of series in which it was tried is presented.

HISTORY

In 1895, Corning first suggested the possibility of introducing an anesthetic solution into the epidural space. In 1905, Cathelin, a French urologist, blocked the sacral and coccygeal nerves through the sacral hiatus (22). Four years later, Stoeckel used caudal anesthesia with some success in obstetrics. His technique was improved upon by Laewen and Schlimpert, in Germany in 1910. In America, Meeker and Bonar used it successfully in gynecology, in 1923, others followed Oldham in 1925, Lundy in 1928, Henry and Jaur in 1929, Rucker in 1930, Campbell in 1935, Johnson in 1936, Sword in 1936, and Baptisti in 1939.

DEFINITION

Caudal block, also known as extradural or epidural block, as defined by Labat, consists in passing a needle through the sacral hiatus and depositing an anesthetic fluid within the sacral canal. The solution is distributed outside of the dura mater and the process is thus differentiated from spinal anesthesia, in which the anesthetic is introduced into the subarachnoid space.

Caudal block is not to be confused with transsacral block, obtained by anesthetizing the sacral nerves through the four posterior sacral foramina, which represent the spaces between the fused sacral vertebrae. Presacral or parasacral block, on the other hand, is the procedure by which needles are passed through the perineum, anesthetizing the sacral nerves at the points of their exit from the anterior sacral foramina by the deposition of the agent into the hollow anterior aspect of the sacrum. A combination of caudal block plus transsacral block is designated as sacral anesthesia.

ANATOMY

Throughout the length of the sacrum, the vertebral or spinal canal is continuous as a prismatic space, 6 to 8 centimeters in length, known as the sacral canal. Following the curvature of the sacrum, its anterior and posterior walls are formed by the fusion of the bodies of the vertebrae, and are perforated by the anterior and posterior sacral foramina, through which the sacral nerves course outward. The dural sac, ordinarily terminating at the level of the second sacral vertebra, constitutes the upper boundary of the sacral canal. The lower end of the sacral canal tapers down to the sacral hiatus, an aperture on the posterior surface of the sacrum, usually comparable in size to an adult's thumbnail. This hiatus, due to the embryological failure of development of the spinous process and the laminae of the fifth sacral vertebra, is usually triangular in shape, the apex being designated by the fourth sacral spinous process while the base is bounded laterally by the sacral cornua, bony projections which articulate with the corresponding coccygeal cornua. Not infrequently the hiatus is found to be diamond-shaped rather than triangular. This impression is received when a tubercle, the rudimentary spinous process of the first coccyx, is prominent in the midline and forms the lower angle of the rhomboid. The sacral hiatus is covered by a fibrous membrane, the sacrococcygeal membrane of Cathelin, and by the lateral sacrococcygeal ligaments. The sacral canal contains a loose areolar tissue in which are embedded the filum terminale, the sacral and coccygeal nerves, and a rich plexus of veins.

PHYSIOLOGY

The pelvic and perineal floors are innervated by the second, third, fourth, and fifth sacral nerves and the coccygeal filaments. Both the sensory and motor fibers of these are anesthetized in the sacral canal and, as in spinal anesthesia, the sensory nerves are more readily affected due to their lower threshold for paralysis.

The uterus is innervated by both an intrinsic and an extrinsic nerve supply. The intrinsic plexus, supposedly coursing in the myometrium itself, has been shown to be able to function inde-

In the Department of Obstetrics and Gynecology of Marquette University, Milwaukee Wisconsin and The Department of Obstetrics and Gynecology of Milwaukee County Hospital, Wauwatosa, Wisconsin

pendently of the extrinsic. This has been demonstrated both experimentally in laboratory animals and clinically by the uneventful progress of labor in patients with paraplegia due to cord tumors, transection, or other spinal cord accidents. The intrinsic nerves are influenced by certain factors important for the institution of labor. The hormones, estrogen and progesterone, elaborated by the ovary and particularly the placenta in pregnancy and pitocin, produced by the posterior pituitary, are necessary for the induction and sustenance of co-ordinated contractions of the uterus. Similarly is the intrinsic supply affected by the mineral ion concentration, particularly of calcium, potassium, and magnesium.

In contrast, the extrinsic innervation of the uterus is derived from both the sympathetic and parasympathetic (cerebrospinal) systems, each of which transmits sensory and motor fibers.

The sympathetic fibers are principally motor in function. Originating in the solar plexus, these fibers traverse the superior mesenteric into the inferior mesenteric plexus, where they unite with fibers from the lumbar sympathetics to form the superior hypogastric plexus (presacral nerve) (That this nerve contains sensory fibers is evidenced by the fact that its resection affords relief in primary dysmenorrhea. However labor following excision of the superior hypogastric plexus is unaltered.) The superior hypogastric plexus divides to form the bilateral inferior hypogastrics, the hypogastric nerves, which pass downward and laterally furnishing the main sympathetic root for the pelvic plexus (the uterovaginal plexus, cervical ganglion, or the ganglion of Frankenhauser). Also contributing to the pelvic plexus are branches which are derived from the sacral sympathetic cords and the parasympathetic pelvic nerve, the nervus ergens. This parasympathetic supply to the uterus, the ergens nerve, arises from the second to the fourth anterior roots of the sacral plexus.

From this brief discussion it becomes evident that the pain of labor of uterine origin as well as that due to the overdistention of the pelvic tissues comprising the lower portions of the birth canal, can and will be eliminated by anesthetizing the sacral nerves, as is done in caudal anesthesia, while uterine contractions can continue almost unaffected.

TECHNIQUE

The sacral hiatus is rather easily identified. With the right third finger placed on the tip of the coccyx, the right index finger is passed along the midline toward the sacrum, until the inverted V

shaped depression is palpated. The apex of this triangular site is defined by the fourth sacral spine, while its base is marked by the two lateral cornua. Since the sacrum is an immobile structure, the sacrococcygeal articulation can be recognized with the external finger when the coccyx is moved by a gloved finger inserted in the rectum. To verify the location of the sacral hiatus further one might visualize an equilateral triangle with the base line extending between the posterior-superior iliac spines and the apex falling directly over the site for puncture.

The position in which the subject lies for the injection is optional. In our series, both the lateral decubitus as well as the knee chest position were used with equal success. Although the patient is probably more comfortable lying on her side, the spine assumes a scoliosis, which makes recognition of the bony landmarks somewhat difficult. On the other hand, having the patient kneel, with the elbows drawn as close as possible to the knees, gives the back a symmetrical arch, enlarges the sacral hiatus and exaggerates the anatomical prominences, all of which further facilitate the procedure. Obviously the knee chest position is more embarrassing and awkward to the pregnant mother; yet, because of its many advantages over the lateral decubitus, it is the position given preference.

The anesthetic being used in our clinic is metycaine (Gamma 2 methyl-piperidino-propyl benzoate hydrochloride). It is a white powder readily soluble in water, alcohol, or chloroform. The solutions are stable and retain their potency after sterilization by heating and do not deteriorate on standing. Although experimentally metycaine is more toxic than procaine, clinically this finding has not been substantiated. In its favor it may be said that metycaine-produced anesthesia is more rapid in its onset and is more enduring than that produced with procaine, and that it is a solution with antiseptic properties of its own. Our results, with the use of a 2 per cent

aqueous solution of metycaine without the addition of drenaline, compare very favorably with those obtained by them, who have tried procaine alone in various dilutions, procaine with adrenalin, with sodium chloride, with sodium bicarbonate with quinine with quinine and urea hydrochloride with magnesium sulphate and in many other combinations. In our series, the quantity of the solution used varied from 10 to 30 cubic centimeters but for the most part (357 cases) 5 cubic centimeters was used.

The instrumentarium required consists only of a 5 cubic centimeter syringe and an 18 gauge

Fig 1 1, Fourth sacral spine, 2, sacral hiatus, 3 coccygeal cornu, 4, coccygeal tubercle

Fig 2 1, Sacral canal, 2, sacral hiatus, 3, end of spinal cord, 4, end of subarachnoid space

spinal puncture needle with stylet The operative field is prepared with tincture of iodine or other reliable antiseptic. The sacral hiatus is defined, and the needle is introduced practically perpendicularly into the sacral hiatus. Infiltrating the site for injection with a dermal wheel has been found unnecessary. Penetration of the fibrous sacrococcygeal membrane is announced by a sudden release in the resistance offered, and the point of the needle strikes the anterior wall of the sacral canal. It is then withdrawn a millimeter or two, and the hub is depressed gently, through an arc of approximately 70 degrees, so that the long axis of the needle lies practically parallel to the plane of the sacrum. It is then advanced 3 to 4 centimeters, to insure its presence in the canal. The stylet is withdrawn, the empty syringe is attached and aspiration is attempted. Withdrawal of spinal fluid or blood, signifying penetration of the subarachnoid space or of a vein is an indication for the removal and re-insertion of the needle. The solution is injected slowly, requiring about one minute for 25 cubic centimeters. The development of a tumefaction beneath the skin indicates a subcutaneous rather than an epidural infiltration. The injection completed, the patient is advised to resume the dorsal-recumbent position.

SUBJECTS

In this series of the first four hundred cases in which caudal anesthesia was used, 368 were primiparas and 32 were multiparas. Of the 368

primiparas, 293 were delivered by low forceps and episiotomies, 8 by midforceps and episiotomies (including 1 Duehrssen's incision), 28 were permitted to deliver spontaneously without an episiotomy, 10 delivered spontaneously with a perineotomy, 6 were forceps deliveries without episiotomies, and 20 were breech deliveries—in 4 of which the breech was broken up and extracted. In 17 cases, transverse blades were applied. In 15 of these, Simpson forceps were used, in 2, the Kjelland technique was followed. Seven occiput posteriors failed to rotate after two hours at complete dilatation. Two of these were delivered face-to-pubis, 2 were rotated with Kjelland forceps, 3 were turned, adopting the Scanzoni maneuver. One primipara was delivered by a low cervical cesarean section performed entirely under caudal anesthesia. In one version and extraction, the caudal block was found insufficient and was of necessity augmented by ether. Two of those delivered without an episiotomy sustained a first degree laceration. Two of the primiparas had twin pregnancies. Of the 32 multiparas, 9 had outlet forceps and episiotomies, 4 had a mid-forceps delivery, 3 were rotated by the Scanzoni operation, 8 were permitted to deliver spontaneously, 4 were delivered by low forceps without an episiotomy, and 2 had assisted breech deliveries. In one patient, caudal was administered for a Voorhees bag insertion, and in another a low

cervical cesarean section was performed entirely under caudal anesthesia.

In this series of 400 cases were 4 cardiacs, 2 patients with moderately advanced pulmonary tuberculosis, and 2 eclamptics.

RESULTS

Within the first 5 minutes after the anesthetic is administered, the outcries of the woman in the throes of labor are suddenly stilled, and the parturient, who only moments before had been writhing in pain, becomes quieted. Since the excitomotor reflex, due to pressure of the presenting part on the perineum, is abolished, the patient loses the urge to bear down. Instead, she becomes mentally at ease and physically comforted. Yet the rhythmic uterine contractions continue painlessly with the same frequency and duration as before, although, it is our impression, somewhat diminished in their intensity. The last-mentioned observation is not reliable, we admit, since the impression was obtained only by palpating the contracting uterus and observing its effect on the progress of labor. Several minutes after analgesia is obtained, anesthesia of the perineum develops. In tests for the loss of cutaneous sensation, which were made by grasping the skin with an Allis forceps, the development of anesthesia was consistently found to begin in the region of the anus and then spread fanwise upward toward the symphysis pubis, backward over the sacrum and gluteal regions, and laterally along the inner aspects of the thighs—the sum effect being a typical ‘saddle’ anesthesia. Simultaneously the musculature of the pelvic and perineal floors becomes completely relaxed. Even in primiparas, the lubricated examining hand can easily be admitted for such obstetrical manipulations as manual rotations, decompositions, and the like. Such relaxation greatly facilitates the application of forceps and reduces the incidence of vault tears. Sensation in and control of the lower limbs is unaffected. Caudal anesthesia has no effect whatsoever on the fetus. Furthermore, the third stage of labor is unaltered, as in only one instance was more than a simple Cr  d   of the uterus necessary for the expression of the placenta. We believe, in fact, that the blood loss is less than that accompanying a delivery under ether anesthesia, since the relaxing effect of the ether on the myometrium is absent. The return of sensation occurs inversely to the direction in which it extended—beginning at the periphery of the saddle zone and advancing concentrically toward the anus. The postpartum period is unaltered.

In all but 13 of this series, the anesthetic was administered at complete cervical dilatation. In the first of these, it was given to a multipara at 3 centimeters’ dilatation, to determine the effect on the progress. This was our first failure. In the second, it was administered at 6 centimeters’ dilatation, with the anterior lip of the cervix impinged between the advancing head and the symphysis pubis. The edematous cervix was liberated and forceps were applied. In the third and fourth cases, primiparas, fetal distress became evident at 6 and 8 centimeters dilatation, respectively. Manual dilatation was done and the infants were delivered with midforceps. The fifth case was a sextigravida, with an acute upper respiratory infection. The caudal block was done at 8 centimeters dilatation, and she was permitted to deliver spontaneously. In the sixth case, a primipara, low forceps were applied earlier because of increasing signs of maternal exhaustion. In the seventh case, labor was terminated at 8 centimeters dilatation because of a co-existing lobar pneumonia. In the eighth and ninth cases, multiparas, forceps were applied through an almost completely dilated cervix, because of heart disease; neither of these two had antepartum cure; one was admitted in labor with aortic fibillation and the other with mitral heart disease, gave a history of having been decomposited during the second trimester. In the tenth case a primipara, progress in the first stage was arrested in midpelvis by an obstructing calcified vaginal cyst. In the eleventh case, the cervix was undilated. A Voochees bag was inserted to institute labor medical induction having failed. The twelfth and thirteenth cases were elective cesarean sections and naturally the cervixes were not dilated at the time.

Obstetrical analgesia, morphine and scopolamine, was administered to only 110 of the 400 cases. The omission of a narcotic was purposeful, since competent and reliable co-operation of the patient was desired in so far as volunteering accurate information as to the subjective effects of the caudal block on uterine and perineal pain.

Complementary anesthesia ether was given to 22 of the patients. Eleven were the cases in which the caudal block had failed completely. Ten experienced traction pains during forceps delivery necessitating ether for the delivery of the head only; the episiotomy repairs were done under the effects of the caudal block. In 1 case complementary ether anesthesia was required when it was found that the caudal block gave insufficient relaxation for an internal podalic version and extraction.

QUANTITY OF SOLUTION

In 10 of the patients, 20 cubic centimeters was injected, in 5 cases, 50 cubic centimeters was used, in 27 cases, 35 to 40 cubic centimeters administered, in 1 instance, only 10 cubic centimeters was given, in the remaining, 25 cubic centimeters was used. The patient who had received only 10 cubic centimeters experienced sufficient "traction" pain to require complementary ether. Generally speaking, for ordinary obstetrical procedures, no advantage was observed when either greater or lesser quantities than 25 cubic centimeters was injected.

ONSET OF ANESTHESIA

The shortest latent period between the time of administration of the anesthetic and the time when anesthesia became evident about the anal region was 2 minutes, the longest was 20 minutes, the average of the series was 7.4 minutes. Generally speaking, it was observed that approximately the same period of time was required for the complete extent of the anesthesia to develop from the time it first became evident, as had elapsed from the time the solution was injected to the time anesthesia was first noted.

DURATION OF ANESTHESIA

The longest period of anesthesia was 3 hours, the shortest, 36 minutes, the average for the series was 1 hour and 29 minutes.

AREA ANESTHETIZED

Consistently, the area over the sacrum and the gluteal regions, as well as the inner aspect of the thighs, was anesthetized, but the height to which the anesthesia rose on and above the vulva varied. Imagining the length of the vulva from the fourchette to the symphysis pubis being trisected into equal zones, it was found that when 25 cubic centimeters of metycaine was injected only the lowest (posterior) zone was affected in 1 case, only the two lower zones in 16 cases, and that the anesthesia extended up to and including the clitoris in 34.3 of the remainder. In 3 cases, anesthesia was observed to have extended from the level of the tenth dorsal spine to the toes, in 3 cases, it included the area from the level of the xyphoid to the knees.

That the quantity of solution injected has a definite relationship to the height to which the anesthesia rises on the anterior abdominal wall is evidenced by the fact that, except for 2 cases in which it did not ascend beyond the symphysis pubis, all 32 cases in which 35 cubic centimeters or more of solution was administered developed

anesthesia to the level of the umbilicus or higher, in several cases, in fact, it rose to the level of the xyphoid. Therefore, we conclude that, with the larger quantities, the anesthetic solution dissects its way under pressure in the extradural space to bathe the nerves at higher levels in the spinal column.

Taking advantage of this phenomenon, which we have discovered only in the recent past, we have extended the use of caudal anesthesia in obstetrics to cesarean sections, and in the gynecological service we have adopted it for selected laparotomies.

RESULTS

We were able to classify our results as follows:

- ++++ (4 plus) Anesthesia of the perineum. Loss of contraction pain.
- +++ (3 plus) Anesthesia of the perineum. Patient aware of contraction pain.
- ++ (2 plus) Anesthesia of the perineum. Loss of contraction pain. Patient experienced pain when traction with forceps was applied.
- o (o) Complete failure.

Guided by these criteria, the results could be grouped numerically as follows:

	Cases
++++ (4 plus)	348
+++ (3 plus)	31
++ (2 plus)	10
o (o)	11

Failures are usually due to inability to locate the sacral hiatus. Very obese women, in whom thick, soft tissue pads obscure the anatomical landmarks of the back and patients with deformities of the lower spine are, obviously, poor candidates for even an attempt at caudal block.

EFFECT ON VASOMOTOR SYSTEM

Realizing the occasional untoward effects of spinal anesthesia on the blood pressure, the influence of the epidural infiltration was closely watched. Sphygmomanometer and pulse readings were taken before the injection, during, and after, the delivery. Variations were inconsistent. In the greater number of cases, the blood pressure had not fluctuated more than 15 millimeters of mercury, in a few, the pressure had risen, in a few, a fall was observed. Other than the normal variations, i.e., the rise accompanying the pains and the expulsion efforts of the delivery, and the fall upon its termination, no remarkable influence of the metycaine on the blood pressure was noted. Similarly, no consistent abnormal influence of the caudal block on the maternal pulse was observed.

SIDE EFFECTS

Immediately after the injection of the anesthetic agent had been completed, 5 of the patients developed transitory episodes of disorientation accompanied by clonic convulsions, most marked in the upper extremities. The longest seizure lasted 3 minutes, following which, as with the others, labor was completed uneventfully. Five others became disoriented and apprehensive for several minutes after the administration of the drug. No tremors or convulsions accompanied their reaction. For want of a more satisfactory explanation, we surmise that these reactions were due to individual sensitivity to the drug. The untoward vasomotor respiratory and gastrointestinal symptoms and signs, such as tachycardia, palpitation, hyperpnea, pallor, nausea and vomiting, as reported by others, were not observed in any of our series. It is our deduction that such side effects may well be due to the epinephrine which the others had added to their anesthetic agent.

CONCLUSIONS

Caudal block offers a feasible and efficacious anesthesia for operative obstetrics. It permits the uterus to contract painlessly, it relaxes the pelvic floor and anesthetizes the perineum. It is harmless to both the parturient and her newborn. It permits the normal separation of the placenta and involution of the pelvic organs. All the untoward side effects of inhalation anesthesia are absent—there is no excitement stage, no nausea or vomiting, no danger of explosion. It lends itself well to an obstetrical service in which drop-ether possibly administered by an untrained interne or nurse, is the only other available anesthesia. It can be used without fear in patients with pulmonary cardiac, or renal complications.

The accompanying drawings are by Mr. Leo C. Massopust.

PUTRID EMPYEMA

HERBERT C MAIER, M D , F A C S , New York, New York,
and EDWIN J GRACE, M D , F A C S , Brooklyn, New York

IN most discussions of suppurative pleuritis little or no distinction is made in the treatment recommended for various bacteriological types of pyogenic empyema. Only tuberculous empyema is considered as a distinct entity. Yet due to certain differences in the pathology of an anaerobic empyema from that of an aerobic infection of the pleural cavity, important modifications in the plan of treatment are necessary for the former group. Clinically it is easy to differentiate an aerobic from an anaerobic empyema in most instances. The common aerobic pleural infections yield purulent fluid which has no offensive odor. The pus in anaerobic pleural infections is usually very foul, and for this reason anaerobic empyema is also called putrid empyema.

The importance of certain fundamental principles in the treatment of aerobic empyema has been definitely established. The necessity of avoiding open thoracotomy in the early stages of a suppurative pleurisy has been stressed because it may lead to collapse of the lung and mediastinal displacement. After the suppurative pleuritis has been present for a sufficient length of time, the inflammatory reaction causes stabilization of the mediastinum and fixation of the lung, and open thoracotomy is then well tolerated. Observations on the thickness, specific gravity, or amount of sediment of the aspirated fluid have been used as clinical guides as to the time when open thoracotomy could be safely employed. Therefore, in general we regard the thickness of the pus as a criterion of the degree of mediastinal stability and pleural thickening. Although these observations on the pus are a very useful and valuable clinical guide in the treatment of aerobic empyema, the dictum to delay open thoracotomy until the pus is thick should not be applied to anaerobic empyema. Early open thoracotomy is indicated in anaerobic empyema regardless of the consistency of the purulent fluid. In putrid empyema the pus may remain thin for a long time. The marked toxicity of many of these patients, due to the type of pleural infection present, necessitates early drainage. The fact that the pus in anaerobic empyema continues to be thin for a considerable time in some cases does not mean that little pleural thickening is present or that the mediastinum fails to stabilize. *In anaerobic empyema the con-*

sistency of the pus is an unreliable guide as to when open thoracotomy may be performed with safety. As the anaerobic pus causes marked toxicity, and as repeated aspiration of the foul fluid with a needle is very dangerous because of the frequency of severe thoracic wall infections, these cases must be treated somewhat differently than aerobic empyema. This does not mean that the same fundamental principles of treatment are not applicable to both aerobic and anaerobic empyema, the principle of avoiding mediastinal flutter and pulmonary collapse applies to all cases of empyema. In anaerobic pleural infections, however, the thickness of the pus and mediastinal stability are not closely correlated due to the pathology of putrid empyema. Neuhof and Hirshfeld (3) emphasized the importance of recognizing putrid empyema as a distinct type of pleural infection because of the special pathology and therapeutic problems involved. They recommended early surgical drainage by open thoracotomy as the preferred method of treatment.

During a period of 2 years (1939-1940) 23 cases of putrid empyema were treated on the thoracic surgery service of Kings County Hospital. This group does not include any cases of anaerobic empyema following surgical intervention in the thorax.

Besides the group of cases analyzed in this paper the authors have observed a considerable number of cases of putrid empyema in other clinics. The poor results obtained when thoracotomy was delayed prompted the present study and plan of therapy.

Age. The patients in our series ranged from 19 to 72 years of age. Nineteen of the 23 cases occurred in the age group from 30 to 70. The average age of the patients was 47 years. The condition was encountered most frequently in the sixth decade of life. Although there were no cases of putrid empyema in children in this series, the condition does occur in childhood. Neuhof and Hirshfeld (2) reported 17 cases of anaerobic pleuritis in a series of 184 cases of empyema in children. The therapy for children and adults is similar.

Sex. In our series 20 of the 23 cases, or 87 per cent, were males, and 3, or 13 per cent, of the cases were females.

ETIOLOGY

Putrid empyema is usually secondary to intra pulmonary disease. Bronchiectasis, pulmonary abscess, and suppurative pneumonia are the most common primary conditions. Anaerobic empyema may also result from perforation of the esophagus, mediastinitis, and penetrating wounds of the thorax, or follow surgical contamination of the pleural cavity during lobectomy, pneumococ-tomy or drainage of a pulmonary abscess. A foul empyema may also be secondary to a subphrenic infection which has perforated the diaphragm. In these latter cases, however, a somewhat different group of bacteria are encountered.

The almost constant association of foul dental sepsis with putrid empyema secondary to intra pulmonary disease led one of us (E. J. G.) to associate with the late Dr. C. Coulter to study the bacteriology of the pyorrheal pockets and the material from the intrapulmonary lesion. In a small number of cases the same organism, a very virulent anaerobic haemotoxin-producing streptococcus, was isolated from both lesions. Dr. Coulter's untimely death interrupted this work, however, he believed that this organism acted as a singularly virulent factor in producing anaerobic intrathoracic suppuration.

In many cases of ruptured pulmonary abscess a putrid pyopneumothorax results due to a free communication between the empyema and the intrapulmonary abscess cavity and hence with the bronchial tree. The etiology of the pleural infection in this group is obvious. There is another group of cases in which no bronchopleural fistula is present. In this latter group the pleural infection is probably due to the rupture of a minute subpleural abscess, which is so small that no bronchial communication with the empyema cavity is established. The pleura is infected by a direct extension from a similar type of infection in the underlying lung. More or less extensive pneumonia may be present. In a considerable percentage of these cases there is a history of bronchiectasis preceding the acute illness. In most instances in which such a history is lacking, the infection in the lung and secondarily in the pleural cavity is due to aspiration of infected secretions from the mouth and upper air passages.

A mixed bacterial flora is usually present in anaerobic empyema. Fusiform bacilli, spirochetes, and anaerobic streptococci are the most frequent findings. Other organisms, including aerobes, may also be present. Symplosta seems to be an important factor in the action of these organisms. It has been shown experimentally by

Smith that a combination of organisms is necessary to produce a foul-smelling abscess in man.

In every case in our series in which anaerobic cultures were made, anaerobes were demonstrated to be present in the pus. Streptococci were the most frequently demonstrated organism, both as the aerobic and anaerobic cultures. Hemolytic streptococci were found more frequently than nonhemolytic streptococci in both the aerobic and anaerobic cultures. *Staphylococcus aureus* was also frequently present and often grew both aerobically and anaerobically. Fusiform bacilli were frequently demonstrated on direct smear of the pus and sometimes on culture. *Spirilla*, *Staphylococcus albus*, *Bacillus proteus*, *Bacillus subtilis*, pneumococci, bacilli of the colon group and some unidentified bacteria were also found.

SYMPTOMATOLOGY

On the basis of their history cases of putrid empyema may be divided into two groups. In the one group there is expectoration of foul sputum which indicates the presence of an anaerobic suppurative process. The sputum may come from an intrapulmonary focus, such as a pulmonary abscess or bronchiectasis, or from an anaerobic empyema with bronchopleural fistula. In the second group the foul sputum is absent and the symptoms may suggest an ordinary pneumonia rather than a suppurative process either in the lung or the pleural cavity.

The majority of cases of putrid empyema have a history of previous intrapulmonary infection. There may be a history of a chronic productive cough, and the sputum may be purulent and at times foul. These are mostly cases of chronic bronchiectasis or chronic pulmonary abscess. In other cases the history suggests an acute pulmonary abscess which then ruptures into the pleural cavity. The severity of the symptoms at the time the empyema develops depends chiefly on whether a localized or extensive empyema results. When the perforation of the pulmonary abscess is into a localized portion of the pleural cavity there may be little change in the patient's symptoms. When an anaerobic abscess ruptures into the free pleural space, the symptoms may be very acute and the patient's condition becomes rapidly worse. In some instances the patient may no longer raise sputum due to drainage of the contents of the abscess into the pleural cavity.

In those cases of putrid empyema without a history of acute pulmonary suppuration, the symptoms suggest a pneumonia. The acute illness is usually characterized by malaise, fever and pain in the chest. There may be a cough which is

MAIER, GRACE PUTRID EMPYEMA

dry or productive of mucoid sputum, sometimes cough is absent. Occasionally the sputum is rusty or frankly bloody.

A definite history of chronic cough preceding the acute illness was recorded in slightly over half of our patients. We feel, however, that if the history had been more carefully taken, a considerably larger percentage of patients would have been found to have had a cough before the acute illness. In some instances the cough was productive of purulent sputum, but only a few patients gave a history of foul expectoration in the past. Several patients had had previous attacks of pneumonia, and one patient had pneumonia repeatedly. In one instance the pulmonary disease dated back to a foreign body which had remained in the bronchus for several months before it was removed endoscopically 18 months prior to the development of the empyema.

DIAGNOSIS

When a putrid empyema is secondary to an acute pulmonary abscess, the diagnosis is usually not difficult if the intrapulmonary focus has suddenly ruptured into the free pleural space. More frequently, however, there is only an encapsulated empyema associated with the pulmonary abscess, and the diagnosis may be difficult to make. The change in physical signs and roentgen studies may indicate the presence of a secondary empyema. Sometimes the co-existing empyema is diagnosed only at the time of thoracotomy.

It is in the cases of putrid empyema without evident previous intrapulmonary suppuration and without foul sputum that the diagnosis is often delayed. At the time of onset of the acute illness a diagnosis of pneumonia is usually made. Certain atypical features may be noted. The sputum may not be rusty, and although a lobar pneumonia is frequently diagnosed, it may be found difficult to type the sputum. Early in the course of the illness the physical signs may suggest the presence of pleural fluid. Roentgenograms may reveal findings consistent with pneumonic consolidation or pleural effusion. The density is frequently interpreted as pulmonary consolidation when it is chiefly due to pleural fluid. The mediastinum is less likely to be displaced in anaerobic empyema than in aerobic empyema because previous pulmonary disease is frequent in the former group and tends to fix the mediastinum.

Most of the patients in our series gave a history of a rather sudden onset to the acute illness. Chest pain was complained of at some time in almost every case. Twenty of the 23 patients had a cough. In 13 cases the cough was productive, but

only 5 patients had foul sputum. In each case of foul sputum there was either an associated pulmonary abscess of appreciable size or a bronchopleural fistula. Only 3 patients had bloody sputum.

A preliminary diagnosis of pneumonia was made in most of the cases. In 4 instances, a pulmonary abscess was diagnosed. Over half of the patients received one of the sulfonamide drugs before the diagnosis of empyema was made. These chemotherapeutic agents do not give the typical dramatic response in this type of infection. In fact the failure to respond to the sulfonamides is a point in the differentiation of the atypical pneumonia associated with a foul empyema from the typical pneumococcus pneumonia. About half of the patients were regarded to be critically ill at the time of admission to the hospital.

The diagnosis of putrid empyema is definitely established by the aspiration of foul pus or foul air from the pleural cavity. Due to the previous intrapulmonary disease causing pleural adhesions, the empyema may be somewhat loculated. We have seen considerable delay in making the diagnosis in several cases due to an anterior location of the empyema. Low aspiration should be avoided because the diaphragm may be elevated as a result of the previous intrapulmonary disease. If the needle traverses the diaphragm, subphrenic infection may result. A spreading subphrenic infection due to this cause was present in one of our cases and it has also been observed by Neuhoef and Hirshfeld (3). A similar complication in aerobic empyema is very unusual. In 2 instances in which the diagnosis of a putrid empyema was made very early, the aspirated fluid was clear and serous, but the overlying air was foul. The odor is therefore present early.

Smears of the aspirated fluid should always be done, usually a variety of organisms will be found. Special examination with the darkfield microscope should be done for spirochetes. Aerobic and anaerobic cultures should be planted. Improper and incomplete examinations of the pus may result in a failure to identify the anaerobic organisms, and hence the occasional laboratory report that this foul fluid is sterile! One does not need to await the report of the culture of the pus, however, to know that immediate surgical intervention is indicated. If tuberculosis were also present, open thoracotomy would still be indicated except in rare instances.

TREATMENT

The importance of immediate treatment in cases in which an anaerobic pulmonary abscess

has ruptured into the free pleural space has been recognized for some time. These patients are best treated by open thoracotomy.

In an anaerobic empyema without clinically demonstrable pulmonary abscess and without bronchopleural fistula, there is usually unwarranted delay in instituting proper therapy. Open thoracotomy with rib resection should be performed as soon as the diagnosis of putrid empyema is confirmed by aspiration. There may be a rare case in which it may be advantageous to delay the thoracotomy for a day or two because of a massive fluid accumulation with mediastinal displacement. In such an instance an incision under local anesthesia should be made through the skin, subcutaneous tissues, and deep muscles of the thorax down to the ribs and intercostal muscles at the site of the exploratory aspiration. This incision should be made within a few hours of the first aspiration. Further aspirations are done through the open wound, which is packed with zinc peroxide gauze. Of course some cases of anaerobic empyema may be aspirated repeatedly without a thoracic wall infection developing but the incidence of infections following thoracentesis is quite high and, when once developed, the thoracic wall phlegmon is of such severity that aside from intrapulmonary disease it is the most important factor in the mortality in these cases. This is entirely different from the situation in aerobic empyemas, in which, with proper technique, infection in the thoracic wall is relatively uncommon following thoracentesis, and, if infection develops, it can usually be easily controlled by simple measures.

The reasons for the serious and frequent thoracic wall infections with anaerobic empyema are several. The pus is often watery in character and, therefore, can leak through a small needle track. Secondly we are dealing with anaerobic organisms which are likely to gain a foothold in a puncture wound in which conditions are favorable for their growth. The ease with which appreciable amounts of this infected fluid leak through the needle track in the intercostal muscles has been convincingly shown at operation when the pleural cavity is needled after the chest wall incision has been carried down to the ribs. The fact that gross leakage of the pus occurs and that it gravitates downward from the puncture site beneath the deep thoracic muscles is shown by the location of the infection in the thoracic wall, which may extend almost entirely in a downward direction from the aspiration site.

Surgical drainage of thoracic wall infections following aspiration of an anaerobic empyema

may be delayed because a cellulitis rather than an abscess is diagnosed. The pus usually collects just outside the ribs and beneath the thoracic muscles. Therefore tenderness and some swelling may be the only indication of chest wall infection. Redness of the skin may be absent. Fluctuation is usually not demonstrable because of the deep site of the purulent collection. For these reasons several days may elapse before the chest wall infection is considered ready for incision and drainage. By this time extensive gangrenous infection of the deep tissues of the thoracic wall may be present. We have seen extensive necrosis of the tissues within a day of a thoracentesis which yielded thin foul pus. The periosteum of ribs and scapula may be destroyed with resultant osteomyelitis.

As mentioned previously with very few exceptions, a thoracotomy with rib resection is performed under local anesthesia as soon as the diagnosis is made. The patient is placed in such a position on the operating table as not to flood his bronchial tree with pus in those cases with free bronchopleural communication. In a considerable number of cases the only safe position is with the patient sitting upright. The surgeon himself should supervise the placing of the patient on the operating table so the proper position for that particular patient may be chosen.

A long incision is made through the area of aspiration. Care is taken not to undercut the muscles. A rather long segment of one or occasionally more ribs is removed. The empyema cavity is opened cautiously because of the possibility of pulmonary collapse. Although the mediastinum is usually stable, precautions must be taken in the event that this should not be the case. If there is sucking of the wound associated with mediastinal shift, the patient should be promptly rolled over onto a large wet dressing as this will markedly diminish the flow of air through the opening. Although we have always been prepared to do this, so far we have not found it necessary. The pus is removed by suction and the presence or absence of bronchial fistula noted. Occasionally the opening into a pulmonary abscess is enlarged. Large rubber tube drains are inserted. It is imperative that no sutures whatsoever are inserted in the thoracic wall. A single suture inserted for the purpose of anchoring a drainage tube may result in a spreading thoracic wall infection of a serious nature. Adhesive strapping may be employed instead. The edges of the wound should not be strapped, as the large opening is a great asset. The chest wall wound is packed with gauze soaked in zinc peroxide. In small empyema

MAIER, GRACE PUTRID EMPYEMA

cavities without bronchopleural fistula, zinc peroxide has also been placed in the pleural cavity. Zinc peroxide is of great value in the treatment of anaerobic thoracic infections (1).

Twenty-two of the 23 patients in this series were treated by thoracotomy with rib resection and open tube drainage. Two of the patients had an incision made in the chest wall down to the ribs a few days before the open thoracotomy was done. In one case the pleural cavity was not drained surgically because this patient died in diabetic acidosis a few hours after a phlegmon of the chest wall was drained.

Because of previous unsatisfactory results when open thoracotomy was delayed in cases of foul empyema, most of the patients in this series were treated by rib resection shortly after the diagnosis was made by thoracentesis. Half of the patients were operated upon within 24 hours of the first aspiration. The delay in most of the other cases was due to the fact that the patient was not immediately transferred to the surgical service. Eighteen of the 23 patients had only a single thoracentesis before thoracotomy. Two patients were aspirated more than twice, both of these patients died.

At the time of open thoracotomy the pus was thin in 9 cases and thick in 14 cases. The lung was partly adherent to the lateral thoracic wall in 17 of the 23 cases. In the remaining cases the empyema was extensive. In 8 of the 9 cases in which the pus was thin at the time of thoracotomy, the lung was prevented from complete collapse by adhesions to the thoracic wall. In the single case in which the pus was thin and the lung was not adherent when thoracotomy was performed, the lung re-expanded well after operation. Therefore, in this series of cases the drainage of putrid empyema when the pus was thin did not result in any difficulty with mediastinal shift or late re-expansion of the lung.

Chest wall infections developed before thoracotomy in 4 of the 23 cases, or an incidence of 17 per cent. This does not give a true picture of the danger of this complication in putrid empyema, however, because most of the cases in this series had a thoracotomy performed shortly after a single aspiration. Three of the four thoracic wall infections developed after a single aspiration and were clinically manifest within 24 hours of the only thoracentesis. The other case had three aspirations performed. Two of the 4 patients with phlegmons of the thoracic wall died. Both of these fatal cases also had diabetes mellitus, and the chest wall was not drained until 4 days after the thoracentesis. In the 2 cases with chest

wall infection that recovered, the thoracic wall was drained the day following the chest aspiration. In 3 of the 4 cases of phlegmon the fluid aspirated from the pleural space was thin. In the single case with thick pus, many fusiform bacilli and other anaerobes were found in the purulent material.

Various complicating conditions were present in addition to the pulmonary and pleural infection. Two patients had diabetes mellitus. Four patients were cardinals, and 2 of these were decompensated before thoracotomy. One patient had a toxic hepatitis and acute tonsillitis with cervical adenitis. Several had general arteriosclerosis and chronic nephritis.

POSTOPERATIVE COURSE

With proper early operation the prognosis is good as far as the pleural infection is concerned. The foul odor may be gone within 24 hours. The patient may show remarkable improvement. If there is extensive intrapulmonary suppuration, this will be the most important factor in prognosis. Oxygen therapy should be used freely.

The chest wall wound often has a necrotic appearance unless zinc peroxide packing is inserted into the thoracic wall wound. This agent is most effective in these anaerobic infections. Care should be taken to prevent the drainage opening from contracting down too quickly. The retention of a very small amount of pus may cause quite a febrile reaction. If a bronchopleural fistula is present, drainage should be prolonged.

The use of sulfonamides seems to be of benefit in some cases. We have employed chemotherapy in several cases in which there was a febrile course after operation apparently due to residual pulmonary infection. Before ascribing the fever to intrapulmonary disease, one must ascertain that the pleural drainage is entirely satisfactory. At the time of drainage of the empyema it may be difficult to evaluate the extent of the intrapulmonary suppuration. If putrid sputum persists after operation, it should be ascertained whether this comes from an undrained pleural pocket with bronchial communication or from the lung. Some mucoid sputum may persist for a considerable length of time.

Painful swollen joints have been present in several of our cases in the postoperative period. In 2 instances the joint pains were associated with fever for several weeks, but the onset of these symptoms was more than a month after adequate drainage of the empyema.

Most of the patients continued to be febrile for considerable periods of time after the empyema

was drained. This was thought to be chiefly due to the slow subsidence of the intrapulmonary infection. Less than half of the patients became afebrile within 3 weeks of thoracotomy. Several continued to be febrile for almost a month and in 4 cases the temperature became normal only from 6 to 7 weeks after the empyema was drained. In view of the slow subsidence of the intrapulmonary infection, and because we did not wish to discharge these patients while the empyema cavity was of sufficient size to require a drainage tube, the period of hospitalization was prolonged. Most of the patients remained in the hospital for a period of 2 to 4 months from the time of admission.

RESULTS

Three of the 13 patients died, giving a mortality of 23 per cent. One patient died as a result of multiple pulmonary abscesses and an extensive phlegmon of the chest wall which followed a thoracentesis done 4 days before the thoracotomy. This same patient also had an anaerobic subphrenic abscess on the same side and diabetes mellitus. Death was chiefly due to the extensive intrapulmonary suppuration. The second death occurred as a result of diabetic acidosis which was not controlled because of a chest wall phlegmon and an undrained anaerobic empyema. In this case we feel that early drainage of the empyema

before the chest wall became infected might have resulted in a successful outcome. The third death was also in a case in which thoracotomy was delayed, and there was an undrained pulmonary abscess.

All 10 patients who recovered obliterated the empyema cavity after thoracotomy and their wounds healed. None required any further surgical procedures as far as the empyema was concerned. Some of the patients continued to have chronic cough and sputum due to the persisting intrapulmonary disease.

CONCLUSIONS

1. Putrid empyema should be differentiated from aerobic empyema.
2. Thoracentesis in cases of putrid empyema is associated with considerable danger of a serious thoracic wall infection.
3. Early open thoracotomy is the treatment of choice in putrid empyema.

MAMMARY CARCINOMA

A Review of 2,636 Cases

IAN MACDONALD, M D, Los Angeles, California

TO augment the already voluminous and frequently repetitive literature on mammary carcinoma is an act which one should contemplate with considerable misgiving. More articles have been published on the subject of carcinoma of the breast than on any other single regional form of cancer. A greater number of radical surgical procedures have been performed for mammary cancer than for all types of malignant lesions of the entire gastro-intestinal tract (24). The accessibility of the breast, its predilection toward the development of both benign and malignant lesions, and the complex pattern of its hormonal control have made its problems a matter of interest to investigators in widely separated fields. Nevertheless, the accumulation of knowledge concerning mammary cancer has not produced any commensurate degree of agreement among research workers or clinicians as to its problems, either epidemiological, etiological, or therapeutic.

The present study is based on a review of 2,636 abstract clinical records of carcinoma of the breast in the cancer archives of the American College of Surgeons. Although the College established the cancer archives primarily as a repository for the abstract records of "cured" cancer cases, the material reported here includes 1,511 5 year "cures" and 1,125 cases in whom recurrences or metastases developed within the 5 year period. Contributed by many institutions and individuals in the United States and Canada during the past decade, this material is obviously not susceptible of analysis by methods used in the review of consecutive cases in a single institution. Any attempt to evaluate the therapeutic methods used in such a collected series would be particularly fallacious for this and other reasons meriting wider recognition.

The number of cases included in this study is sufficiently large to make possible an evaluation of certain factors of interest in the genesis, prognosis, and management of mammary carcinoma. The factors studied are seven in number: age, family history of cancer, childbearing, lactation, known duration of tumor, stage of disease at treatment, and the survival of "cured" cases after the 5 year

period. All of the cases included in this study are recorded as having had histological confirmation of some form of mammary carcinoma. Instances of sarcoma of the breast, and of carcinoma in the male breast, have been excluded. "Five year cure" cases are arbitrarily defined as those in whom a minimum period of 60 months has elapsed following treatment without clinical evidence of recurrence. Practically all of the records studied were submitted on the abstract cancer record form recommended by the cancer committee of the American College of Surgeons, the uniformity of which greatly facilitates this type of study. Unfortunately, as shown in Table I, the variability of detail in which the forms were completed proportionately determined the number of cases available for analysis of the several factors studied.

AGE

In Figure 1 is presented the comparative age distribution of 1,486 5 year cures and 1,045 recurrent¹ cases, and, drawn to scale, the estimated current cases of mammary cancer by age groups in the white female population of the United States. Table II shows the detailed figures from which this graph was constructed.

The number of cases up to the age of 35 is not sufficiently large to be of real significance. There is, however, legitimate cause for interest in the 13 cases in which patients were under the age of 25 years. Ten of this group were 5 year cures and only 3 were recurrent cases. Most noteworthy is the slight but consistent percentage excess of 5 year cures over recurrent cases in the age period from 36 to 50 years. Past the age of 50, the percentage of recurrent cases is greater, and this unfavorable balance carries through to the most elderly group of 70 and over. The curves, both for the 5 year cures and the recurrent cases, roughly parallel those for the estimated current cases in the general population indicating that age is not an important prognostic factor in cancer of the breast.

Such a conclusion is in sharp conflict with a current attitude recently expressed by Pack and Liv-

¹From the Department of Clinical Research, American College of Surgeons. Bowman C. Crowell, M D, Director.

¹The expression "recurrent cases" is used throughout to designate cases in which recurrence or metastases appeared before the 5 year post treatment period elapsed.

Fig. Percentage age distribution of 486 5 year cures and 1045 recurrent cases.

lingston that cancer of the breast is a much more menacing disease in young women than in mid life or old age. So general has this impression become that there seems to be an attitude in many clinics of adopting less aggressive therapeutic measures in patients under 40 years of age. The rapid course of inflammatory carcinoma of the breast, more common in younger women, and the gravity of mammary carcinoma occurring in the pregnant or lactating patient undoubtedly lend additional weight to this credence. One also has the impression that the statistics from specialized cancer institutions are weighted by the proportion of referred problem cases among younger women.

A number of studies of end results in general institutions have demonstrated that age has little bearing on prognosis (5, 10, 12, 18, 23, 28, 29). The balance of evidence, in fact, indicates a more favorable outcome for patients in the fourth than in the sixth decade. Evans and Leucuth, in a study of 1,300 cases, after corrections had been made for natural factors of longevity found a distinct excess of 5 and 10 year cures in the group under 40 years of age over those in the sixth decade. Lewis and Rienhoff studied the 10 year

end-results of surgical treatment at the Johns Hopkins Hospital from 1889 to 1931 and concluded that no essential variation could be shown for the age groups from 30 to 70 years. An analysis of percentage 5 year survivals⁶ by age groups of 3,740 cases, reported by Harrington in 1935, also demonstrates the less favorable results of treatment in women of 55 to 64 years of age.

The evidence presented here strongly supports the contention that the best results in the treatment of breast cancer are obtained between the ages of 35 and 50. The thesis that an especial virulence exists for mammary carcinoma in the young is not verified.

HEREDITY

Information concerning the hereditary background of cancer patients gleaned from ordinary

number of children borne seems to have little or no influence in prognosis. These conclusions are drawn from the data presented in Table III.

LACTATION

Information concerning the functional activity of the breast was available in only 1,146 of the 1,636 records reviewed. Seven hundred and forty-two 64.8 per cent, of these patients were nulliparous, but this figure is heavily weighted by the paucity of information in the abstract records concerning lactation in parous women. In only 404 records of childbearing women was there any approach to satisfactory information concerning their lactation. In 234 cases, the statement "normal" lactation appeared, and such statements were accepted at face value. It is more than probable however that careful questioning will disclose many abnormalities of lactation in women who maintain uncertain recollections of "normal" lactation (1). One hundred and forty-two of these 404 parous patients either had failed entirely to suckle or during lactation had suffered such aberrations as "caked" breasts, abscesses, and periperal mastitis. Twenty-eight additional patients had nursed less than 3 months after one or more deliveries, compared to the 6 month period of lactation generally accepted as desirable. In practically all instances these abnormalities of lactation affected the breast which subsequently became the site of carcinoma, and in a considerable number the cancerous breast alone had been afflicted by inflammatory disease during lactation.

Using as a standard Walnright's figure that 20 per cent of American women in a control series had not lactated, in Figure 3 is charted the lacta-

tion history of this group of cases. Setting with the 742 nulliparous cases, in 170, or 42 per cent of 404 parous women with breast cancer, the breast had failed properly to perform its physiological function of lactation.

Failure of normal lactation as a factor in the genesis of mammary cancer is a thesis which has received complementary verification from a number of clinical and experimental studies in recent years. Adair and Bagg (1) in a study of 800 cases found only 8 per cent with accurate histories of normal lactation. Walnright found failure of lactation in 40 per cent of 637 patients, compared to only 20 per cent in 541 control cases. Lee reported that 31 per cent of 156 breast cancer cases had never lactated, without mention of abnormalities in lactation. In a tribe of African aborigines whose women habitually nurse their children for 2 to 3 years, Ellis found that mammary cancer was a rare disease.

Notable experimental evidence on this subject has been adduced by Bagg and his co-workers. Bagg's "functional test" in mice consists of rapid breeding of females coupled with prevention of suckling by withdrawal of the litters as early as possible after birth. By this means strains of inbred mice with low spontaneous incidence of mammary cancer have developed a greatly increased ratio of such tumors. In C 57 strains of mice which apparently had not developed a mammary tumor in 10 years of inbreeding the functional test produced mammary tumors in 15 per cent of the animals subjected to this form of physiological stress. Bagg has further increased the incidence of mammary carcinoma in animals by ligation of the terminal ducts. The consequent stasis and ductal distention led to changes in the ductal epithelium which eventually gave rise to infiltrating carcinomas.

Such experimental and clinical evidence as has been presented makes possible the statement that failure of the breast to perform properly its physiological function is the most consistent apparent factor in the genesis of human mammary carcinoma. Whether the actual etiological factor is mechanical, due to distention of ducts and retro-tion of secretion (19) or chemical, originating in retained products of lactation or in repeated hormonal stimulation, is beyond the scope of this discussion. Such analyses as are reported here and elsewhere notably by Adair (1) may well lead one to regard normal lactation as a measure of prophylaxis against carcinoma of the breast of which obstetricians and pediatricians should be cognizant. There is a well recognized tendency particularly among urban women, to shirk the

Fig 3 Lactation history in 404 parous patients

Fig 4. Stage of disease at treatment in 1,511 5 year cures

duty of breast feeding, and the frequency with which this practice is condoned and even recommended by physicians is to be deplored. It is entirely possible that the steadily increasing incidence of breast carcinoma in "civilized" women is in large measure due to complete or partial failure of lactation.

KNOWN DURATION OF TUMOR

In Figure 4 is graphically shown the known duration of the breast tumor from first recognition by the patient to treatment in 938 five year cures and 1,007 recurrent cases. The importance of early treatment is well illustrated in the sharp decline in the number of cases amongst the 5 year cures treated from 1 to 11 months after recognition of the tumor. Over the same period of increasing delay, the number of recurrent cases is generally though not consistently greater than that of 5 year cures. It is, however, the institution of treatment within the first 2 months that apparently produces the most appreciable increment in 5 year cures. With a delay of 12 months and over, both groups again show a sharp increase, with the recurrent cases in excess. The appreciable proportion of 5 year cures, 24.8 per cent, treated more than 1 year after the recognition of the tumor probably has a twofold explanation. Most obvious is the fact that the majority of these cases represent the indolent, slowly growing breast carcinomas of low degree malignancy which metastasize late, or occurring in hosts whose desmoplastic reaction to the tumor is intense. More debatable is the concept that some of these carcinomas arose in pre-existing benign lesions of the breast as suggested by the presence of tumors for periods as long as 5 years among the cured cases.

In those patients treated within 12 months after recognition of the tumor, the average period of delay was 3.08 months for the 5 year cures and 4.5 months for the recurrent cases. Of the 5 year cures, 44.6 per cent were treated within 3 months of recognition of the tumor, while 34.2 per cent of the recurrent cases were treated with equal promptness. Treatment was instituted more than 1 year after the tumor was noted in 24.8 per cent of the 5 year cures and 33.3 per cent of the recurrent cases. Thus there is a definite inverse relation between delay in treatment and chance of cure, though not as pronounced as one might expect.

Otherwise stated, 44.6 per cent of the 5 year cures were treated within 3 months, and 28.5 per cent 12 months or more after recognition of the tumor. Thus 73.1 per cent of all of the 5 year cures were treated either very early or very late, lending point to the natural division of breast cancer into 2 general groups: those which metastasize early and those which remain a localized disease for long periods of time. Recognizing in addition the fact that in a certain proportion of the cured patients treated early the tumors are of the slow growing type, one is confronted with the conclusion that in spite of the importance of early treatment in eradicating certain early lesions, end-results are determined more by natural selection than by early treatment. In general terms, this analysis indicates that of every 4 instances of 5 year cures of carcinoma of the breast, 2 are treated within 3 months, 1 from 9 to 12 months, and 1 more than 1 year after recognition by the patient.

FIVE YEAR "CURE" CASES

Stage of disease at treatment The stage of the disease at the time of treatment in the 1,511 cases

Fig. 5. Known duration of tumor

of 5 year cures is shown in Figure 5. The classification used is that recommended by the cancer committee of the American College of Surgeons

Stage A. Disease limited to breast.

Stage B. Questionable involvement of axillary nodes.

Stage C. Axillary nodes involved.

Fig. 6. Percentage distribution of 869 cases, 6 to year cures.

Stage D. Supraclavicular nodes involved.

Stage E. Remote metastases present.

In this study only those cases in which there had been microscopic confirmation of axillary node metastases were classified as Stage C. In 175 cases, 11.6 per cent, the records failed to provide adequate information on this point, and in view of the known inaccuracy in clinical judgment as to the presence or absence of axillary involvement (11) these cases were designated as Stage B.

The feature of interest in these figures is that 33.4 per cent of this large number of 5 year cures were histologically proved to be Stage C cases, a fact of the greatest clinical importance. Further,

majority of the cures classed as Stage B were those in which the presence of clinically positive axillary nodes was recorded but in which the microscopic confirmation was lacking. If one accepts Greenough's statistics that 90 per cent of the clinical Stage C cases are confirmed by the pathologist as such, then the proportion of Stage C cases in this cured group will approach 40 per cent. One series has been reported in which 50 per cent of 5 year survivals were Stage C cases (21). The inference is plain that to deny patients with operable growths the chance of radical treat-

Fig 7 Deaths from cancer and other causes after 5 years, 238 cases

ment because of the presence of axillary metastases is therapeutic defeatism at its worst

In general terms, it seems evident that of every ten 5 year cures, not more than 6 are Stage A at the time of treatment, usually the other 4 are Stage C, and very occasional patients will survive 5 years or more without recurrence when the disease has involved the supraclavicular nodes. This is not to imply that all patients in the Stage C group should be regarded as candidates for radical mastectomy, for their therapeutic management demands the utmost nicety of clinical judgment, based on a number of factors beyond axillary involvement *per se*. In fact, there are criteria of operability within the Stage C group, and many cases in this series are examples of the failure properly to apply such criteria. The point, however, must be made, that almost 40 per cent of 5 year cures will accrue from the proper management of Stage C cases, and consistent therapeutic indolence in these cases will result in the loss of 4 of every possible ten 5 year cures.

Survival For the purposes of this study, a 5 year post-treatment period free from recurrence or metastasis has been used as a criterion of cure. There are certain forms of cancer with a predilection toward delayed recurrence so notable as to make the arbitrary 5 year period a poor gauge of therapeutic success. Basing his opinion upon a follow-up study of 167 cases, Bartlett concluded that "what happens after the fifth year is relatively unimportant," stating that only 1 patient died in the second 5 years. There is no small amount of evidence opposing this conception. Ducuing reported a progressive decrease in survivors from 8

per cent at the end of 5 years to 2.2 per cent in the thirteenth year. From the fifth to the fourteenth years Lewis and Rienhoff followed 322 cases, the survivors decreasing from 30.9 per cent to 8.7 per cent, the maximum loss occurring by the ninth year. Matthews made a 10 year follow-up study and concluded that a patient surviving the first 5 years had a 62.5 per cent chance of living 10 years, and that deaths between 5 and 10 years were mainly from cancer rather than from intercurrent disease. Survivors in Perry's series of 653 cases decreased from 28 per cent at 5 years to 16 per cent at 14 years. In 419 cases of recurrence reported by Pfahler and Vastine, 7 per cent appeared more than 5 years after treatment. Breast cancer has recurred more than 30 years after treatment.

In this series, 1,207 cases were reported at a time when they had been free of disease for 6 or more years, and of these 869 were 6 to 10 year survivors, 264 were 10 to 15 year survivors, and 74 for more than 15 years. The curve of survival for the 869 cases of 6 to 10 year survivors is shown in Figure 6. In Figure 7, plotted against Daland's statistics of survival in 100 untreated patients, are the mortality curves for 238 cases in which the time and cause of death is known, for those dying both of recurrence and intercurrent disease. It is evident from these graphs that the number of reported survivors and the deaths from cancer, both in treated and untreated patients, level off after the ninth year. As a true gauge of end-results, therefore, the 5 year yardstick is best replaced by one in which curative achievements are measured on the basis of 9 or 10 year statistics.

SUMMARY

The records of 2,636 cases of mammary carcinoma, 1,511 5 year cures and 1,125 recurrent cases, have been reviewed. Comparative statistics are presented for the factors of age, childbearing, and the known duration of tumor. Collective data concerning the influence of heredity and lactation in the genesis of the disease are analyzed. The stage of disease at treatment and the survival period of the 5 year cures are separately presented.

CONCLUSIONS

The age of patients with mammary carcinoma does not have the prognostic significance with which it is commonly accredited. Excluding the cases of "inflammatory" carcinoma and those occurring in gravid and puerperal women, more common in the young, carcinoma of the breast at any early age merits as radical an approach with as much chance of cure as in older women. The best results are obtained in those patients who are 35 to 50 years of age, and the least favorable in the decade from 50 to 60.

There is evidence of an inherited susceptibility to cancer in approximately 20 per cent of this series, but among the relatives of those women having an hereditary background of cancer there is an excess of breast cancer at least 3 times greater than in the general population.

Nulliparae are more prone to develop cancer of the breast than women who have had children but once developed the prognosis is as good, or perhaps better for the nulliparous woman. The number of children borne by parous women has little or no influence on prognosis.

The most consistent apparent factor in the genesis of mammary cancer is the failure of the breast to perform its expected physiological function. A full period of lactation in childbearing women seems to offer a degree of protection against subsequent development of breast cancer.

Early treatment is of utmost importance in the cure of certain early lesions predestined otherwise to undergo rapid growth and early dissemination but in general end results are determined more by natural selection than by early treatment. Tumors of long duration in themselves are no contra-indication to radical treatment, for 25 per cent of the 5 year cures here recorded were treated more than 1 year after recognition of the tumor.

To deny patients with otherwise operable neoplasms the chance of radical treatment because of the presence of axillary node metastases is to for the possible loss of 40 per cent of attainable 5 year cures. Criteria of operability exist within Stage C (II) cases, requiring consideration of combined methods of therapy.

The 5 year post treatment period as an arbitrary standard for the evaluation of therapeutic measures is inadequate for mammary carcinoma, and may well be replaced by a minimum 9 year period.

CARCINOMA OF THE COLON AND RECTUM

A Study of Metastasis and Recurrences

CHARLES W MAYO, M D, F A C S, and CARL P SCHLICKE, M D,
Rochester, Minnesota

SUCCESS in the management of cancer of the colon and rectum customarily is evaluated in terms of survival rates over arbitrarily determined periods. Unfortunately, from the standpoint of the accuracy of such estimations, factors other than the cancer per se may act to curtail survival. A patient who has had his cancer completely extirpated may succumb to a pulmonary embolus a week later. As far as this individual patient is concerned, the treatment has been a failure although from a purely technical standpoint it was highly successful. However, had the patient not fallen victim to an unfortunate postoperative complication, the most important thing in determining his survival would have been the success attending the efforts of the surgeon to eradicate the cancer.

The present study concerns itself entirely with the technical side of the problem, namely, the ability of the surgeon to rid the patient of cancer. The influence of metastatic growths, their distribution in the body, the accuracy with which their presence can be detected by the surgeon, and, finally, the question of recurrence will likewise be considered.

MATERIAL

During the 5 year period beginning January 1, 1935, and ending December 31, 1939, 334 patients suffering from carcinoma of the colon and rectum died and were subjected to postmortem examination. The material employed in this study was obtained from the clinical records and protocols of the necropsies of these patients. Only cases of primary adenocarcinoma were considered. (This excluded 1 squamous cell epithelioma of the rectum, 1 sarcoma of the cecum, 1 case of Hodgkin's disease of the cecum, and 3 cases of carcinoma secondary to lesions elsewhere in the digestive system.) The distribution of the lesions was as follows: rectum, 83 cases, or 24.9 per cent, rectosigmoid, 41 cases, or 12.3 per cent, sigmoid, 77 cases, or 23.1 per cent, descending colon, 18 cases, or 5.4 per cent, splenic flexure, 10 cases, or

3.0 per cent, transverse colon, 13 cases, or 3.9 per cent, hepatic flexure, 11 cases, or 3.3 per cent, ascending colon, 24 cases, or 7.2 per cent, cecum, 29 cases, or 8.7 per cent, and 28 cases of multiple carcinomas, or 8.4 per cent. This distribution corresponds in general to the clinical distribution encountered at the Mayo Clinic and elsewhere (Lockhart-Mummery). The incidence of multiple carcinomas is higher than that reported by Bagen and Rankin or Schweiger and Bagen, owing to the fact that we included 8 cases of multiple polyposis with multiple malignant lesions and 5 cases in which two or more low grade polypoid malignant lesions were present.

FINDINGS

Metastasis. In order to determine the total incidence of metastatic growths and their distribution, the findings of the surgical pathologist at the time of operation (in those cases in which patients were subjected to surgical procedures), as well as those of the pathologist who made the postmortem examination, were consulted. Only those tissues showing microscopic as well as gross evidence of invasion were listed as sites of metastasis. It is to be remembered that these figures represent totals and are therefore higher than the surgical or postmortem figures alone. The findings appear in Table I.

The highest total incidence of metastasis occurred in cases of carcinoma of the transverse colon, followed by those of the rectosigmoid and splenic flexure, while the lowest incidence occurred in those of the hepatic flexure. When lesions of the transverse colon and multiple lesions are excluded, the incidence of metastasis is found to be 4.9 per cent higher from the left portion of the colon than from the right portion of the colon. The highest incidence of involvement of the regional lymph nodes occurred with carcinoma of the rectosigmoid, the second highest with carcinoma of the cecum, and the lowest with carcinoma of the splenic flexure. Carcinoma of the rectosigmoid likewise led in the incidence of hepatic metastasis. Metastasis to the lungs and pleura most commonly followed carcinoma of the rectum.

TABLE I.—INCIDENCE AND DISTRIBUTION OF METASTATIC GROWTHS

Site of primary tumor	Rectum	Recto-sigmoid	Sigmoid	Distal ileo-caecum	Sigmoid flexure	Transverse colon	Hepatic flexure	Ascending colon	Cecum	Multiple tumors	Total
Cases	83	43	77	28	20	3	23	84	39	36	364
Per cent without metastasis	44.6	56.3	37.7	44	30	83	54.5	41	41	41	5
Per cent with metastasis	55	40	61	55.6	70	17	45.5	59	59	59	359
Per cent of total Regional nodes	43	38.5	44	38.9	30	33.3	36	30	35	33.6	
Distant nodes	6	4	5		30	7.7		8.3		6	
Liver	7	27.7	36	11	30	5	27.3	30.8	13.8	17	
Lungs and pleura	16	7.5	8	6			9	17.5	30	30	
Other	13	34.4	36	6	30	23.3	17.5	27.5	32	30.7	36
Per cent showing local invasion	58.9	51.9	44	30	70	61.1	36.4	22.2	45.2	77.9	39

Peritoneal implants were found in 11.7 per cent of the cases. Other sites of metastasis included the jejunum or ileum, 6.6 per cent, omentum, 4.5 per cent, adrenals, 3.9 per cent, ovaries, 3.6 per cent, stomach, 3.0 per cent, pancreas and bladder, 2.4 per cent each, colon, 2.1 per cent, spleen, prostate, ureters, and diaphragm, 1.8 per cent each, mesentery, abdominal wall, and kidneys, 1.5 per cent each, duodenum, gall bladder or bile passages, bony skeleton, 1.2 per cent each, mesenteric, portal or hepatic veins, fallopian tubes, 0.9 per cent each, wound, uterus, vagina, iliac veins or vena cava, 0.6 per cent each, skin or subcutaneous tissue, sympathetic ganglia, mesenteric artery, rectum, myocardium, and brain, 0.3 per cent each. In most of the cases in which visceral metastasis occurred, involvement of the lymph nodes was noted, but this was not a constant finding.

In addition to metastatic implants, the tendency to local invasion is indicated in Table I. Invasion was said to have occurred when there was histological evidence of serosal involvement or penetration to adjacent tissues by the carcinomatous process. This is seen to have taken

place most commonly in cases of carcinoma of the splenic flexure and least commonly in cases of multiple tumors.

A more detailed investigation of metastatic growths in the liver was carried out to ascertain whether the site of the primary tumor had any influence on the location of the implants in the liver. It will be recalled that lesions of the left portion of the colon were more common than those of the right, and that the incidence of metastasis was slightly higher from the left portion of the colon than from the right. There were 74 cases in which metastatic growths occurred in the liver. In 5 cases—4 of which came from lesions of the rectum or sigmoid—these were confined to the left lobe. In 3 cases they were predominantly in the left lobe, in 48 cases there was diffuse involvement of both lobes. In 4 cases the right lobe was chiefly involved, and in 14 cases it was exclusively involved. In other words, involvement of the right lobe preponderated in 24.3 per cent of the cases, of the left lobe in 75.7 per cent.

Recognition of metastatic growths. In order to determine the degree of accuracy with which the surgeon was able to recognize the presence of

TABLE II.—EVIDENCE OF EXTENSION OF CARCINOMA IN GROUP OF CASES IN WHICH NO EXPLORATION WAS CARRIED OUT (Postmortem findings)

Therapeutic class	Cases	Per cent of cases without metastasis	Per cent of cases with metastasis	Per cent of cases with regional nodes involved	Per cent of cases with hepatic metastases	Per cent of cases with other metastases	Per cent of cases with local invasion
No operation	18	55	44		30	54.5	30
Emergency operation	18	44	55.6	44	33	33	33
Follow-up or irradiation or both	44	44	55	33	44	44	33
Incidental postmortem finding	21	95		8			3
Total	79	51.4	54	40	30	32.4	36

TABLE III—CASES IN WHICH ABDOMINAL EXPLORATION WAS CARRIED OUT

Operative procedure	Cases	Findings	Per cent of cases in which no metastasis was found	Per cent of cases in which metastasis was found	Per cent of cases with regional nodes involved	Per cent of cases with hepatic metastasis	Per cent of cases with other metastasis	Per cent of cases with local invasion
Exploration only	13	Operation	30.8	69.2	0	53.8	38.5	0
		Necropsy	15.4	84.6	69.2	69.2	61.5	46.2
Palliative operation	38	Operation	26.3	73.7	23.7	42.1	42.1	68.4
		Necropsy	5.3	94.7	60.5	37.9	68.4	71.1
Preliminary operation	44	Operation	81.8	18.2	2.3	(4.5?)	11.4	(38.6?)
		Necropsy	47.7	52.3	34.1	11.4	27.3	36.4
Total	95	Operation	52.6	47.4	10.5	26.3	27.4	45.3
		Necropsy	26.3	73.7	49.5	37.9	48.4	51.6

metastatic growths at the time of operation, an analysis of the cases was made on the bases of the procedures to which each patient was subjected. The cases were divided into two main groups. The first consisted of 70 cases in which no exploration was carried out. This included 22 cases, 6.6 per cent of the total, in which no operation was performed, 18 cases, 5.4 per cent, in which emergency operations were performed because of obstruction or perforation of the bowel and in which exploration was not feasible, 9 cases, 2.7 per cent, in which treatment was given by fulguration or irradiation or both, and 21 cases, 6.3 per cent, in which the tumors were incidental findings at postmortem examination. The second group consisted of 264 cases in which opportunity was afforded for exploration of the abdominal cavity by the surgeon. This group included 13 cases, 3.9 per cent, in which exploration alone was carried out, 38 cases, 11.4 per cent, in which palliative¹ procedures were carried out, 44 cases, 13.2 per cent, in which preliminary operations—such as colostomy or ileocolostomy in anticipation of subsequent resection—were performed, and finally, 169 cases, 50.6 per cent, in which presumably curative operations—resections—were performed.

Since the cases in the first group afforded no opportunity for the surgical recognition of metastatic growths, the postmortem findings alone were presented in Table II, chiefly for comparison with the findings in the second group. As would be expected, the highest incidence of cancerous extension, by local invasion or by metastasis, occurred in the group of cases in which no operation was performed because of the debility of the patient or clinical evidence of widespread metas-

¹Operations were designated as palliative not only when, because of local extension or the presence of metastasis, no attempt was made to remove the tumor and decompression or short circuiting alone was established, but also when resections were carried out in the presence of obvious metastatic growths in the liver or extensions of the tumor which could not be removed.

tasis. Likewise, the lowest percentage occurred in the group of small and unsuspected early carcinomas which were incidental postmortem findings.

In the group of cases in which the opportunity for exploration was afforded, a comparison of the operative and postmortem findings in the cases in which exploratory, palliative, or preliminary operations were performed is presented in Table III. The surgeon's opinion regarding local invasion and all metastatic growths except those in the liver was credited only when borne out by the findings of the surgical pathologist. In the case of metastatic growths in the liver the surgeon's opinion was recorded regardless of confirmation, which was seldom practicable. The average length of survival after operation was 43.7 days after exploration, 66.3 days after palliative procedures, and 16.8 days after preliminary operations. Marked discrepancies are seen to exist in the incidence of involvement of the lymph nodes between the operative and postmortem findings. These can be explained by the fact that in comparatively few of the cases in this group were the regional nodes removed for examination by the surgical pathologist. The ability of the surgeon to detect metastatic growths in the liver was fairly accurate, as will be shown later. The discrepancy in the case of other metastatic growths is due to the fact that only those which lay within the peritoneal cavity could be detected readily. Local invasion is seen to have occurred in 71.1 per cent of the cases in which palliative procedures were performed and in only 5.3 per cent of these cases were there no metastatic growths. The high incidence of metastasis—52.3 per cent—in cases in which patients were subjected to preliminary operation is of interest, as it indicates that many of these cases would not have been suitable for resection had the patients survived.

TABLE IV—CASES IN WHICH CURATIVE RESECTIONS WERE PERFORMED

Survival after operation	Cases	Operative findings					Postmortem findings				
		Evidence of spread of tumor	Per cent of cases	Mode of spread to cases with extension			Per cent of cases in which no metastasis was found	Per cent of cases in which metastasis was found	Distribution of metastases		
				Local	Nodes	Other			Nodes	Liver	Other
More than 30 days	25	No extension	24				28.0	41.7	25	16.7	25
		Extension	66	76	53.8	3	20	30	26	15	25
		Total	100				28.0	41.7	26	15.8	25
31 days or less	131	No extension	38				89	17.6	7.8	3	1
		Extension	61	66	66.8	30	65	22	13	19	12.5
		Total	100				71.8	26	8.4		1.1
Total	69	No extension	27.3				77.8	22	12	7.9	6
		Extension	66	64	65	13	61.3	23.7	1	11.5	14
		Total	100				67.8	23.7	1	10	14.8

In Table IV are seen the findings in those cases in which supposedly curative operations were performed. There were 169 such cases. These were divided into two groups, those in which death occurred within 3 weeks of operation—131 cases—and those in which survival exceeded 3 weeks—38 cases, in some of which the patients lived several years after operation. In the latter group of cases, the surgeon found no evidence of extension of the tumor beyond the confines of the bowel in 13 or 31.6 per cent, of the cases. In 7 or 58.3 per cent, of those in which no extension was found, no metastatic growths were found at necropsy. In the remaining 5 41.7 per cent, metastatic growths were found at necropsy involving the lymph nodes in 3 25.0 per cent, the liver in 2 6.7 per cent, and other regions in 3 cases, 25.0 per cent. Residual carcinoma was found in 3 cases, 16.7 per cent. In the 26 cases in which the surgeon found evidence of extension—local invasion in 30 cases, metastasis to nodes in 14, metastasis elsewhere in 6—no metastatic growths were found at post mortem examination in 13 cases, 50.0 per cent. Metastatic growths found in the 13 remaining cases were located in the lymph nodes in 7 cases, 53.8 per cent, the liver in 4, 15.4 per cent, and elsewhere in 2 38.5 per cent. Recurrent or residual cancer was noted in 3 cases, 11.5 per cent.

The most interesting group of cases from the standpoint of the study at hand is the group in which resection was carried out and death occurred within 3 weeks of the time of operation, as the result of postoperative complications, such as shock, hemorrhage, pneumonia, peritonitis, or pulmonary embolism. The findings in those cases

presumably should differ very little from the conditions left by the surgeon at the conclusion of the operation, at least in so far as the status of the tumor is concerned. In this group of 131 cases, the surgeon found no evidence of extension in 31 cases, 38.9 per cent. When these 31 cases came to necropsy no metastatic growths were found in 42, or 83.4 per cent. Of the 9 remaining cases, 17.6 per cent, the pathologist found metastatic growths in lymph nodes in 4, or 7.8 per cent, in the liver in 3, or 5.9 per cent, and elsewhere in 1 or 2.0 per cent. Residual carcinoma was found in 2 cases, 3.9 per cent. In the 80 cases, 61.1 per cent, in which the surgeon found evidence of extension—local invasion in 48 cases, metastasis to lymph nodes in 55 cases, and other metastasis in 8 cases—52, or 65.0 per cent, were free of metastatic growths at postmortem examination. In the 28 remaining cases, 35.0 per cent, metastatic growths were found in lymph nodes in 9 cases, 11.3 per cent, in the liver in 8 cases, 10.0 per cent, and elsewhere in 11 or 13.8 per cent. Residual carcinoma was detected in 5 cases, 6.3 per cent. Considering all cases in which resection was carried out, the surgeon found no extension in 37.3 per cent, of these 77.8 per cent were free of metastatic growths at necropsy. He found extension in 62.7 per cent and 6.3 per cent of these were free of metastatic growths at necropsy. Residual carcinoma was found in 7.1 per cent.

The responsibility of recognizing metastatic growths does not fall on the surgeon alone. Pelmonary skeletal, certain hepatic metastatic growths, and many others often can be discovered by the clinician or roentgenologist and the patient

may be spared futile and unnecessary operations. On the surgical pathologist rests the duty of identifying involved lymph nodes and of confirming gross evidence of visceral metastasis. Next to the regional nodes, the liver is the site in which metastatic growths are found most frequently. Since biopsy of suspicious tissue in this organ is not practicable routinely, the discovery and recognition of carcinomatous implants fall to the surgeon. With what degree of aptitude the surgeon meets this responsibility, the following study indicates.

In the entire series of 334 cases, there were 260 in which adequate opportunity for exploration of the liver by the surgeon was afforded. In 224 of these he considered the liver to be free of metastatic growths, in 12 there were areas which he regarded with suspicion, and in 24 cases, he felt that metastatic growths definitely were present. Of those cases in which the surgeon thought the liver was not involved, postmortem examination revealed an uninvolved liver in 197 cases, or 87.9 per cent, and a carcinomatous liver in 27, or 12.1 per cent. In the cases in which the surgeon was in doubt, the pathologist found metastatic growths in 6, or 50.0 per cent and none in 6, or 50.0 per cent. In those cases in which the surgeon believed metastatic growths to be present, the pathologist confirmed the impression in 22, or 91.7 per cent, but did not confirm it in 2 cases, or 8.3 per cent.

Factors contributing to recurrence. The most common cause of so called recurrence, in the broad sense of the term, probably is the failure to remove some portion of the primary growth or some of its secondary colonies. It is questionable, but possible, that in some cases implants may occur by contamination during the process of extirpation. But a very common cause, which usually does not receive the attention it merits, is the presence in the remaining segments of the bowel of areas bearing malignant or potentially malignant growths which have been wholly unsuspected. In the group of 169 cases in which curative resection was carried out, independent cancers were found in the bowel at necropsy in 7 cases, or 4.1 per cent.

Although unanimous agreement is not yet forthcoming as to the relation of adenomatous polyps to carcinoma of the large bowel, there is little room for doubt that in many cases the rôle played by polyps is more than coincidental. This impression certainly was borne out by the present study. Adenomatous polyps were found in 114, or 34.1 per cent, of the 334 cases reviewed. In these 114 cases, definite malignant changes were recognized in the polyps of 16, or 14.0 per cent. The ade-

nomatous polyps occurred singly in 54 cases, multiple polyps were noted in 52 cases, diffuse polyposis coli existed in 8 cases. In 15 cases the polyps were confined to the rectum, in 20, to the sigmoid, in 8, to the descending colon, in 10, to the transverse colon, in 7, to the ascending colon, and in 10, to the cecum. In 39 cases they were distributed over several segments. In 5 cases their location was not noted.

For purposes of comparison a review was carried out of 100 consecutive postmortem examinations performed on adults who had died of diseases other than carcinoma of the large bowel. Their ages ranged from 22 to 80 years, with an average age of 54.7 years. Polyps were present in 16 cases, 16.0 per cent. Eight of these, 50.0 per cent, showed beginning cancerous changes.

The true importance of adenomatous polyps appears when one considers the group of cases in which death occurred within 3 weeks of resection. Any polyps found in this group of 131 cases in all probability were present at the time of operation. They were found at postmortem examination in 49 of these cases, or 37.4 per cent. In 7, or 14.3 per cent, malignant changes had occurred.

OBSERVATIONS

Extension of carcinoma of the colon and rectum may take place by local invasion, via the lymphatics or via the blood stream. Extension is the chief factor influencing operability. Local infiltration is the most common form and spread by the other routes is said to occur relatively late. The extent of spread by the respective routes varies with different portions of the colon. We found local invasion most common with lesions of the splenic flexure, a fact which probably accounts for the high mortality rate attending removal of growths in this region. Invasion occurred with 28.9 per cent of the rectal carcinomas. Barger and Larson noted it in 109 of 447 cases of rectal carcinoma. Attachments most commonly result from inflammation but, in our series, only cases in which actual invasion of the tumor was demonstrated were included.

We found regional nodes involved in 47 per cent of our cases. There was no progressive segmental increase or decrease extending from one end of the colon to the other. Boyd stated that spread is slowest in the distal portion of the colon and danger of recurrence is greatest in the proximal portion because of the more abundant lymphatics associated with the absorptive function of the latter. Rankin (21), on the other hand, found metastatic growths most common in the distal portion of the colon, least common in the proximal

portion, and attributed this distribution to the protective influence exerted by the lymphatics. We found involvement of the regional lymph nodes most common with carcinoma of the rectosigmoid—58.5 per cent—but almost as common with cecal lesions—55.2 per cent. Craig and MacCarty found the lymph nodes involved with 32 per cent of the carcinomas of the cecum, while McVay found involvement with 47 per cent of rectal carcinomas. These figures were based on operative specimens and, accordingly, are lower than ours. However, Glöckner and David found 68 per cent nodal involvement in their painstaking study of specimens of carcinoma of the rectum removed at operation.

Examination of the regional lymph nodes at the time of operation is of great importance in establishing a prognosis. Many attempts have been made to discover factors influencing nodal involvement. Naturally the longer a growth has been present, the greater the likelihood of extension. Rankin and Broders found that the incidence of nodal involvement paralleled the grade of the tumor—based on histological evidence of differentiation. Bacon and Gilbert stated that invading types of lesions are most likely to metastasize and Hayes, in his study of 100 cases of colonic cancer, found metastasis least common with growths which protruded into the lumen of the bowel.

Visceral metastatic growths were most common in the liver—the lungs and pleura coming second. Such metastatic growths occurred most often from carcinoma of the rectum or rectosigmoid in our series. This was in accord with the observations of Harding and Hankins, who also noted the tendency of rectal lesions to produce visceral metastasis. Involvement of such structures as the bladder, other segments of the alimentary canal, and the abdominal wall was usually by direct extension rather than true metastasis. Ovarian involvement was sometimes by direct extension, sometimes blood-borne, giving rise to a Krukenberg tumor. Visceral metastatic growths may be chiefly lymph-borne or blood-borne. It generally is stated that evidence of nodal involvement is the most reliable indication of the presence of visceral metastatic growths. Rankin and Broders found the incidence of visceral metastasis paralleling the grade of the primary lesion. Brown and Warren, however, expressed the belief that the most valuable index of all is evidence of vascular invasion, as determined by careful study of 3 regions of the primary tumor. They noted visceral metastasis with 41 per cent of 170 cases of rectal carcinoma. In many of these cases no evidence of nodal in-

volvement was found but in only 1 case did visceral metastasis occur in the absence of local intravascular invasion.

Our study of the distribution of metastatic growths in the liver was not particularly fruitful. Injection experiments by McIndoe and Connors and others have suggested that the right and left lobes of the liver are anatomically independent as regard to their blood supply and excretory ducts. Such work has given rise to the question of the existence of a dual portal current, blood from the superior mesenteric vein (jejunum, ileum, and right portion of the colon) passing mainly to the right lobe, and blood from the frenal vein (splenic, left portion of the colon, rectum, and spleen) passing to the left. Although metastatic growths were most commonly diffuse, regardless of the site of the primary lesion, when there was a preponderance, it occurred more than twice as often in the right lobe as in the left, although lesions of the left portion of the colon and rectum were far more common than those of the right portion of the colon. This discrepancy could not be accounted for by a difference in the relative weights of the two lobes, which it is said rarely exceeds 50 grams.

In considering the problem of ridding the patient of his disease, only the group of 69 cases in which resection was carried out need be reviewed. In only 37.3 per cent of these cases was there no evidence of extension at the time of operation. Lymph nodes were involved in 40.8 per cent, involvement of overlying peritoneum or adjacent tissues had occurred in 40.8 per cent, and other metastatic growths were found in 8.8 per cent: 65.1 per cent, 64.2 per cent, and 3.2 per cent, respectively of the cases which showed extension. In spite of this comparatively high incidence of extension, no metastatic growths were found at postmortem examination in 67.5 per cent and recurrent or residual carcinoma in only 7.1 per cent. In the group of 13 cases in which survival was 3 weeks or less and in which conditions presumably differed little from those at the completion of operation, it is found that, when no extension was noted at operation, metastatic growths could be discovered in only 17.6 per cent at postmortem examination and residual carcinoma in only 3.9 per cent. Furthermore, of the cases in which extension was noted at operation, only 35 per cent showed metastatic growths at necropsy and 6.3 per cent residual cancer. Obviously minute undiscovered metastatic growths may have remained, but the fact that gross evidence of cancer remaining anywhere in the body was absent in so high a proportion of cases after opera-

tion, even though extension was known to have occurred, reflects considerable credit on the efforts of the surgeon. In the group in which survival exceeded 3 weeks, sometimes by several years, an increase of 19.2 per cent in the incidence of metastatic growths was found at necropsy, distant metastatic growths which were beyond the scope of surgical intervention showing the greatest relative increase. Residual cancer increased 7.9 per cent but recurrences or new cancers probably contributed to this rise.

The foregoing figures and those of the other groups in which procedures other than resection were carried out, likewise furnish a fairly good index of the accuracy with which metastatic growths could be detected at operation. The recognition of metastatic growths is the determining factor in deciding whether an operation is to be an exploration alone or a palliative one, or whether resection is to be attempted, and if the latter, how much tissue can and must be removed. The surgeon overlooked metastatic growths in the liver in only 12.1 per cent of cases. Many of these growths were small and were discovered a long interval after surgical exploration. When suspicious areas were noted at operation, necropsy showed 50 per cent of them to be malignant, and finally, when the surgeon designated the liver as involved, he was correct 91.7 per cent of the time. Lesions in the liver which were potential sources of confusion to the surgeon were revealed at necropsy to include adenomas of the bile ducts, cysts, hemangiomas, tubercles, infarcts, and cirrhosis.

The importance of the presence of additional, independent lesions of the bowel in the development of recurrences has been shown by the findings at necropsy of additional cancers in 7 cases and cancerous polyps in 10 cases in the group in which resection was performed. The rôle of adenomatous polyps may be controversial but their presence in 34.1 per cent of all the cases of carcinoma of the colon and rectum in this study, in contrast to 16.0 per cent incidence in a group of patients of similar age who died from other causes, is suggestive, to say the least. Adenomatous polyps were left after operation in 34.3 per cent of the group in which resection was performed, the incidence of malignant polyps and frank secondary carcinomas being slightly higher in the group of cases in which the survivals were longer. The 50 per cent incidence of malignant changes in the polyps of the control group may seem incongruous at first sight until one recalls that the polyps in the series under consideration were associated with carcinomas in 100 per cent and, when one

speaks of malignant changes in 17.2 per cent of the cases in which polyps were present, one is speaking of polyps still left behind after resection of a full blown cancer.

Just as senile hyperplastic changes develop in the epidermis with advancing age, hyperplastic tendencies develop in the intestinal mucosa. Bagen stated that some form of polypoid hyperplasia of the mucosa is present in 50 per cent of persons more than 30 years of age. The frequency with which polyps occur is difficult to estimate. Clinically, Buie has found them in 1 of every 35 patients undergoing proctoscopic examinations, polypoid lesions are seen in 1.8 per cent of the colons examined roentgenologically at the Mayo Clinic. Pathologically, Stewart has shown that the reported incidence of polyps varies with the care with which they are sought. He found them associated with 29.6 per cent of the cancers of the colon that he studied. Susman found polyps in 6 per cent of 1,100 consecutive postmortem examinations. Only 7 per cent of these polyps occurred in persons less than 40 years of age, although 40 per cent of his cases fell into this age group. Fifteen of his 66 patients having polyps had cancer of the colon and, among 34 cases of cancer of the colon, polyps were present in 15, the peak of incidence of both lesions falling between the ages of 50 and 70 years.

The most suggestive evidence of the relation of adenomatous polyps to cancer is found in the familial cases, although these tend to occur in younger age groups. Rankin (21) stated that cancer of the colon develops in 50 per cent of these cases. FitzGibbon and Rankin, David, and others, by careful pathological studies, have traced the development of cancer from polyps. In examination of patients who had refused to submit to fulguration, Buie has seen carcinoma at the site previously occupied by polyps. Lockhart-Mummery and Dukes described mucosal irregularity adjacent to cancers of the colon, localized areas of epithelial hyperplasia extending several inches away from the growth. They expressed the belief that adenomas represent a more advanced stage of this hyperplasia, which may develop into carcinoma in certain cases. The opinion was also expressed that after carcinoma has developed, hyperplasia and benign tumors regress.

The importance of the submucosal lymphoid aggregations in the production of these epithelial changes has been emphasized by Coffey and Bagen. More recently, an interesting investigation and review of the topic have been reported by Bagen, Cromar, and Dixon.

The origin of polyps sometimes is inflammatory in association with such conditions as chronic ulcerative colitis, tuberculous enteritis, old strictures of the bowel and so forth. Although these often are not true adenomatous polyps, occasionally they are. In 6 of our cases carcinoma of the large bowel developed in association with chronic ulcerative colitis. The question has even been raised whether the polyps occurring in connection with carcinoma of the bowel may not be the result of the irritating influence exerted by the presence of an ulcerating cancer. But hyperplastic and polypoid changes are more common around small, early carcinomas than around large, late lesions, according to Lockhart Mummery and Duke. Yocomans has emphasized the primary importance of irritation and inflammation in the development of polyps and carcinoma. In accord with the old views of Virchow and of Verne

Whether one believes that all cancers of the colon arise from polyps and that all polyps are potentially malignant, or not, there is no denying that accessory growths often are responsible for so called recurrences. The practical importance of this is apparent. Whenever a carcinoma of the colon is encountered, the presence of another malignant or potentially malignant lesion should be suspected and carefully ruled out. Having discovered a carcinoma by proctoscopic examination, the clinician should not settle back in the happy assurance of having fulfilled his obligation to the patient. In the absence of obstruction roentgenologic study of the remainder of the colon should be carried out to eliminate the possible presence of another lesion. The entire colon should be explored carefully by the surgeon at the time of operation. All malignant lesions should be removed. Benign lesions should be removed fulgurated, or kept under faithful observation. In all cases in which resection is performed, follow-up studies should be carried out at periodic intervals. There is considerable clinical and experimental evidence to support the hypothesis that the presence of a cancer inhibits the development of a second cancer. When the primary lesion is removed, this restraining influence disappears and another potentially malignant region may undergo carcinomatous degeneration.

It is beyond the scope of this paper to discuss the influences at work in the production of hyperplastic or malignant changes or changes which normally hold cell growth and regenerative processes in check. Yet the subject is not so controversial but that certain of its connotations should be borne in mind by all who are called on to diagnose and treat carcinoma of the colon and

rectum. Only by thorough and painstaking investigations of each case will avoidable "recurrences," due to accessory lesions, be prevented.

SUMMARY

A clinicopathological study of 334 cases of carcinoma of the colon and rectum has been presented. Regional or distant metastasis occurred in 60.5 per cent of the cases and local invasion in 39.5 per cent. Among cases in which there was hepatic metastasis, no correlation could be found between the site of the primary tumor and the site of involvement in the liver.

The ability of the surgeon to detect metastasis at the time of operation was found to be good. Among cases in which death occurred shortly after resection no metastasis was found at necropsy in 82.4 per cent of those in which none was found at operation. The success of extirpation was revealed in this same group of cases, 65 per cent of those in which there was metastasis at operation being free of it at necropsy. Residual cancer was found in only 5.3 per cent of the cases in which death occurred shortly after resection. In those cases in which the surgeon believed metastatic growth to be present in the liver, the pathologist confirmed the impression in 91.7 per cent.

Independent growths are felt to be responsible for many "recurrences." Polyps were present in 34.1 per cent of the cases in this entire series, in contrast to 16.0 per cent of a control series consisting of patients without cancer of the bowel. In 14.0 per cent of the cases in which polyps occurred, malignant changes were found in the polyps. Multiple carcinomas were found in 8.4 per cent of the cases. Among cases in which resection was carried out, additional independent cancers were found at necropsy in 4.1 per cent.

Whenever a carcinoma is found in any portion of the colon or rectum, the presence of second carcinoma must be carefully ruled out. After operation, the malignant potentialities of the remaining mucous membrane should be borne in mind and careful follow-up studies carried out.

AN ARTIFICIAL ILEOCECAL VALVE

JACOB A. GLASSMAN, M.D., M.S., Chicago, Illinois

IT has been established that the normal ileocecal valve serves two important physiological functions: namely, (1) to avoid too rapid emptying of ileal contents into the cecum, thereby permitting maximal digestion and absorption of food products, and (2) to prevent a reflux of fluids laden with great numbers of bacteria and with toxic end products from putrefaction, into the rapidly absorbing ileum. Besides this protective mechanism furnished by the valve there is, of course, the relatively great abundance of lymphoid tissue, in the form of "Peyer's patches," in the walls of the terminal segments of the ileum. These, as Huntington concluded from his investigations, protect the body from invasion by microorganisms in that stretch of the gastrointestinal tube. It is particularly in the cecum, where the presence of a liquid nutrient medium represented by the fluid intestinal content or feces is conducive to luxuriant bacterial growth that the danger of bacterial invasion is great. That the strain on the protective mechanism of the junction of small and large intestine is considerable is indicated by the frequency with which that lymphoid tissue breaks down with resultant peritonitis and often death.

According to Alvarez and Rankin, the mucosa of the colon, on the other hand, appears to be a very efficient barrier to the passage of toxins into circulation. One of the features that is said to protect the body from auto-intoxication is the dryness of the feces in the middle and descending portions of the colon. About the only place in which absorption of bacteria and their toxins and the end products of protein putrefaction are likely to occur is in the first part of the colon where the fecal material is sufficiently liquid, although toxins that are absorbed here are believed to be slightly altered by the mucosa of the colon and by the liver. Rankin states that "more dangerous and more deleterious to health than the passage of chemical substances is probably the passage of bacteria from the cecum and terminal portion of the ileum into the lymph passages and nodes of the mesentery."

A number of investigators have shown that bacteria are constantly getting through the wall of the bowel and there is evidence that at times,

as may occur after purgation or after intestinal upsets, this grade of infection of the lymph nodes or of the blood stream is severe enough to impair health. Excepting perhaps the mouth and the pharynx, the ileocecal area of the gastrointestinal tract, for the reasons stated, is most vulnerable and most exposed to attack by bacteria and their toxins.

On the basis of the incompetence of the ileocecal valve seen by x-ray examination in some patients with gastrointestinal complaints, the opinions expressed by many roentgenologists differ greatly regarding its significance. Hurst declares unequivocally that the ileocecal sphincter does not prevent regurgitation into the ileum. He has seen barium suspension pass into the ileum when run into the colon at a pressure as low as 1 foot of water. "There can be no doubt," he says, "that the function of the sphincter is, as Keith suggested, to prevent the contents of the ileum from passing too rapidly into the cecum." Barclay and others are of the opinion that the competence or the incompetence of the ileocecal valve is of no significance in diagnosis. Singer and Hitzknecht observed incompetence in numerous cases of obstipation, and this occurred whether the cecum was filled or not. Carmen declares that incompetence of the ileocecal valve is of all degrees, ranging from a trivial backflow to an extensive filling of the lower ileum.

Of those who regard incompetency of the ileocecal valve as a significant factor in diagnosis are Case, Dietlen, Ivy, Carmen, and others. Dietlen states that while the ileocecal valve is incompetent in infants, it is normally competent in children and adults. Case has observed a reflux of ingested barium suspension from the colon to the ileum in many cases and believes that valvular incompetency is a significant abnormality and that it is a common cause of ileal stasis. Carmen doubts that an enema, put into the bowel under unphysiological conditions which necessitate at least a slight degree of hydrostatic pressure, would be a fair test of the physiological competence of the valve. A regurgitation of ingested material into the ileum after once passing the ileocecal valve would, he claims, theoretically have much greater import. Whether incompetency of the ileocecal valve indicates an unimportant perversion or a lack of function or is significant of

struct the normal anatomy, that is, he makes no attempt to reproduce a valve-like structure somewhere in the anastomosis

In the experiments of reproducing intestinal valves that should resemble the true ileocecal valve, dogs were used In addition to developing a technique for the formation of such a valve, I made a preliminary comparative study of the bacterial flora in the small intestine of the animals in which ileocolostomies were made with and without the incorporation of the newly constructed valve

OPERATIVE PROCEDURE

The method described in the following furnishes an ileocolic valve of excellent function, and the experimental cases in which it was introduced and subjected to trial have proved its competency throughout the period of observation In the process of its reconstruction, the valve can be made to project in a given direction, thereby permitting the passage of food substances to take place in that direction only and preventing a reflux in the opposite direction Before the anastomosis of the small and the large bowel is undertaken, the valve-like structure is first formed in the distal segment of the ileum approximately 15 to 20 centimeters from the chosen site of ileocolostomy By constructing the valve first, that is, before opening the bowel, the operator works in a strictly aseptic field

Figure 1, 1, illustrates a piece of small intestine in which a circumferential seromuscular incision is carefully made down to and through the submucosa almost up to the exterior surface of the mucosa With the blunt end of the scalpel, as shown in Figure 1, 2, the severed seromuscular layer is raised by dissection from both sides of the

serious pathology, with possibilities in the way of differential diagnosis, remains to be determined Some surgeons, notably Kellogg, considered ileocecal incompetence of sufficient significance to devise methods for its repair

Physiological studies of the functions of the ileocecal valve have been carried out by such investigators as Ivy, Wright, Starling, Hartridge and Evans, and others Their conclusions are quite in accord with one another, namely, that the function of the ileocolic sphincter is to retain chyme in the ileum until digestion and absorption are completed and to prevent regurgitation of fecal material into the ileum

With the belief that the surgeon does not give sufficient consideration to the physiological significance of an ileocecal valve when he chooses to do reconstructive surgery of the bowel, such as ileocolostomy and ileosigmoidostomy, I turned to the development of a technique for the utilization of a segment of the intestine in the formation of a valve resembling the ileocecal valve grossly histologically, and physiologically

In surgical procedures in which there is need of doing "short-circuiting" operations, such as ileocolostomy and ileosigmoidostomy, the operator after severing the distal portion of the ileum and anastomosing the proximal end to the transverse or the sigmoid colon, invariably fails to recon-

b

Fig. 5. Photomicrographs of stained longitudinal section through the segment of ileum containing the newly formed valve. $\times 50$. a, Section passed through the center or apex of the valve; the absence of the mucosa from one part of

its margin is an artefact. b, Section passed more tangentially through the valve. In both cases the mucosal layer is seen to extend partly into the normal abdominal fold representing the valve.

incision. In the dog, each raised flap needs to be about 1.5 centimeters in extent yet, in every case the extent of the flap depended upon the diameter of the small bowel selected. The flaps are then cut off at their base, as indicated in Figure 1, so that a section of bowel about 3 centimeters in length is now denuded or lacking its seromuscular coat. Knowing the direction in which the protrusion of the valve must point, that is, toward the lumen of the large bowel, the operator proceeds to invaginate the denuded mucosa into the lumen. To achieve the correct pointing of the valvular fold away toward the left, as portrayed in Figure 1, 4 and 5, the interrupted suture employed is placed through the left seromuscular edge (Fig. 1, 3). Then the suture is continued through the right seromuscular layer but approximately 7 to 10 millimeters from its free edge (Fig. 1, 3). The suture is now drawn together and tied (Fig. 1, 4 and 5) while an assistant helps to keep the mucosa invaginated. Several interrupted sutures of black silk, or of chromic catgut (No. 000) are successively placed until the edges of the entire intestinal circumference (Fig. 5) are brought together in such a way that the left edge overlaps the right. This brings about maximum amount of invagination of the circular mucosal fold, which now serves as the valve (Fig. 2) by permitting the intestinal contents to pass toward the colon but preventing their reflux by virtue of its ability to constrict and approximate itself to the point of complete closure.

Because of the frequent postoperative distention (Jones) of the ileum near the point of anastomosis, the chosen site of the valve is safely beyond and should therefore not become incompetent as a result of that distention. Moreover, the ample distance between the anastomosis and the position of the valve provides for a better blood supply on both its proximal and its distal sides. From the photographs (Figs. 2 and 3, a and b) of longitudinal sections of the bowel containing the newly constructed valve it is seen that the latter is a projecting fold with a central core of muscle and submucosa covered on both sides by mucosa.

The mechanical effectiveness and strength of such newly constructed valves were tested in some of the experimental dogs after sufficient time had elapsed to permit healing of the intestinal wounds. Clamps were placed on the bowel some distance (15 cm.) from the valve both proximal and distal to it. Then water was injected under pressure into the distal segment until this became distended. A considerable distention and back pressure was necessary before the valve became incompetent and allowed the water to rush into the collapsed proximal segment of the bowel.

In addition to such experiments, fluoroscopic studies were made on exteriorized bowel segments containing the anastomosis. By means of a Luer syringe, a barium sulfate solution was injected into the colon and observed as it passed into the

loop of anastomosed ileum containing the artificial ileocecal valve. The distal loop of the ileum became markedly distended before the barium was actually seen streaking into the loop of the ileum proximal to the valve. Apparently, the continued distention and the increasing back pressure of the barium rendered the valve incompetent.

Films were taken to illustrate further the efficiency and mechanism by which the return flow of colonic content is prevented from passing beyond the selected site of the artificial ileocecal valve.

In Figure 4, a, an exteriorized segment of colon from an experimental animal was clamped off on both sides of the ileocolic anastomosis and filled with barium sulfate solution. The site of the ileocolic union is seen to be distended, which indicates that the actual point of anastomosis offers no barrier to the reflux of the colonic material into the ileum. On the other hand, the site and actual outline of the artificial ileocecal valve is clearly made out in Figure 4, b. The shadow cast by the barium is bifurcated at the site of the valve, and this contour of shadow results from the fact that the valve is teat-like or cone-like with its apex pointing toward the ileocolic junction. As the barium backed into the space between the protrusion of the valve and the surrounding wall of the bowel, its pressure probably contributed to the closure of that orifice. In the same figure some barium is seen streaking through the valvular aperture.

BACTERIOLOGICAL STUDY

In consideration of the effect of such a valve on the bacterial flora in the intestinal canal proximal to it, a preliminary bacteriological study was undertaken on a group of dogs subjected to ordinary ileocolostomy and on another group subjected to valvular ileocolostomy of the kind just described. Though the number of animals used thus far is too small to permit final conclusions, the results obtained appear to be significant and sufficiently encouraging to urge a continuance of the investigation.

On culture of the material obtained from the dog's ileum, both on Endo's and plain media, *Bacillus coli* was found to be the predominant organism. In several instances *Streptococcus fecalis* was also isolated, but in association with *Bacillus coli* and in numbers far less than the latter. Therefore, the only method available for a comparative study of the bacterial flora in the two groups of animals was a quantitative determination, that is, a count of the number of pure colonies of *Bacillus coli* isolated.

Fig 4 a, An exteriorized segment of colon clamped off on both sides of the ileocolic anastomosis and filled with barium. The actual site of anastomosis offers no barrier to the reflux of the colonic material into the ileum. b, A shadow cast by barium that is bifurcated at the site of the valve, this shadow represents the true contour and direction of the teat like valve.

To obtain the bacteria, 5 cubic centimeters of warm sterile water in a Luer syringe, fitted with a Wassermann needle, was injected into the lumen of the ileum and withdrawn again into the syringe. Samples were taken from 6 consecutive levels, at 30 centimeter (1 foot) intervals, oral of the valve. The samples thus obtained were collected separately in sterile test tubes and cultured the same day.

Six such sample specimens were cultured on both Endo's and plain media, and after 24 hours of incubation the quantitative estimations were made directly from the culture dishes as follows. 1+ was taken to express a growth consisting of from 1 to 25 colonies of *Bacillus coli*, 2+ from 25 to 50 colonies, 3+ from 50 to 100 colonies, or twice the number of the preceding, while 4+ expresses a growth so "heavy" that an accurate count could not be made.

To study the effect of the introduction of the operative procedure, whether it be an ordinary

First or preoperative step: Obtainment of the bacteria as described in the text.

Operation: Ileocolostomy.

Second or postoperative step: Reopening the animal some time later for the withdrawal of bacteria as described.

Ileocolostomy or a valvula ileocolostomy each dog was examined bacteriologically by the method indicated both before and a certain period after the operation. In this way comparative data were obtained for each individual dog, as set forth in Tables I and II. To interpret the results properly the data as a group must be compared, but the preoperative and postoperative states of each dog should be considered as the significant points, since any dog normally may differ from the next in his bacterial flora especially quantitatively. The incorporation of the results from the different animals in the same table is simply a matter of convenience.

By referring to Table I dog 1 is seen that 13 days after an ordinary ileocolostomy was performed the bacterial count rose to more than twice the number of *Bacillus coli* present prior to the surgical operation. Similarly dog 2 also shows a marked increase in its bacterial count 9 days fol-

lowing surgery. At 150 centimeters (5 ft.) it reveals *Streptococcus fecalis* in a considerable number which apparently did not exist there before the anastomosis was made. In dog 3, no particular changes are noticed until the 120 centimeter (4 ft.) level in the ileum is reached. Here after 14 days, the bacterial count rises from 2+ to 3+ thus indicating an increase of approximately two times the number of bacteria originally present. At a point 50 centimeters (5 ft.) it reveals *Streptococcus fecalis* in a considerable number which apparently did not exist there before the anastomosis was made. In dog 3 no particular changes are noticed until the 20 centimeter (4 ft.) level in the ileum is reached. Here after 4 days, the bacterial count rises from + to 3+ indicating an increase of approximately two times the number of bacteria originally present. At a point 150 centimeters (5 ft.) in the ileal segment of the same animal, *Bacillus coli* and *Streptococcus fecalis* ap-

pear, both of which were absent there before the operation. Dogs 4 and 5 exhibit only a comparatively slight increase in the postoperative bacterial count. That a shift of the colonic organisms to abnormally higher levels in the ileum occurs after elimination of the natural ileocecal valve by the usual "short-circuiting" operation is indicated by animals 3 and 5.

Table II embodies the results of the bacteriological examination after the introduction of a valve with the ileocolostomy; this series of dogs shows in general that the bacterial flora either remains unchanged from the normal, or even is reduced, which indicates a favorable effect of the inclusion of the valve. In comparison with the preoperative state, dog 1, for instance, reveals no appreciable bacterial change, 14 days after the

operation, in the entire stretch of ileum examined. Dogs 2, 3, 4, 5, and 6 manifest a variable reduction in bacterial counts after operation. Even a small shift of the *Bacillus coli* organism toward the colon is seen in dogs 2 and 5, an observation which is as favorable a point for the valvular ileocolostomy as the shift in the opposite direction is an unfavorable point for the ordinary ileocolostomy.

In addition to the bacteriological study, general observations of the condition of the animals—appearance, frequency of defecation, type of stool, etc.—after the operations furnished some measure of the relative effects of the two types of ileocolostomy. Of 14 dogs, which were subjected to the ordinary type of ileocolostomy, almost all of them had increased number of bowel move-

ments, liquid stools, and as a consequence the appearance and symptoms of dehydration. On the other hand the dogs in which a newly constructed valve was added to the ileocolostomy showed an appearance and conditions of defecation which deviated little from the normal state.

SUMMARY AND CONCLUSION

The present paper describes a surgical method which utilizes a segment of the intestine for the formation of an artificial ileocecal valve that resembles the normal ileocecal valve grossly, histologically and physiologically. By the addition of such a valve to an ileocolostomy the attempt is made to reconstruct the normal anatomy as closely as possible.

A preliminary bacteriological study revealed that the bacterial flora in the ileum of a dog after a valvular ileocolostomy was performed remained essentially unchanged, and in some instances even showed a smaller number of organisms. This result is in contrast to the findings in cases of ordinary ileocolostomy in which greater numbers of organisms were isolated, and at intestinal levels higher than occurred normally.

Comparison of the general state of the animals after ordinary ileocolostomy with that of animals after valvular ileocolostomy also furnishes evidence that the second or new procedure leaves the animal in a better condition physiologically than the first.

The conclusion is warranted that the introduction of a valve of this kind in ileocolostomies in man can be recommended in surgery.

TREATMENT OF OBSTRUCTIVE HYDROCEPHALUS IN ADULTS

JAMES C WHITE, M D, F A C S, and JOSEF MICHELSEN, M D, Boston, Massachusetts

SURGICAL procedures for the relief of hydrocephalus fall into three principal categories. They are carried out for (1) removal of the cause of obstruction, (2) reduction of the output of cerebrospinal fluid, (3) establishment of a new channel to permit the spinal fluid to escape from the ventricular system and reach the areas of absorption in the subarachnoid space. Methods of removing lesions which block the third and fourth ventricles or compress the sylvian aqueduct are already well known and therefore do not come under the subject discussed in this report. Treatment of the communicating type of hydrocephalus also constitutes a special problem quite separate from the conditions included herein. The type of hydrocephalus which we wish to discuss is produced by inoperable tumors in the region of the third and fourth ventricles or the intervening aqueduct and the still rarer benign occlusions of the aqueduct of Sylvius. Patients with this condition suffer from severe headaches and vomiting, progressive loss of vision from papilledema, and terminal failure of the intracranial circulation and respiratory paralysis.

In the past, treatment of hydrocephalus caused by inoperable tumors has been discouraging, but in recent years two methods of establishing free and lasting drainage of the ventricular system into the subarachnoid space have been described. Five years ago Stookey and Scarff advocated opening the anterior and posterior walls of the third ventricle and permitting the obstructed cerebrospinal fluid to escape into the large suprachiasmatic and interpeduncular cisterns. This operation had already been described by Dandy (3), but his exposure usually necessitated cutting one optic nerve and his results in young children have been unsatisfactory as we shall note. It was also performed by Cushing in at least one patient and the operation was illustrated in a sketch. The results are not mentioned, but the Peter Bent Brigham Hospital records state that 2 years later the patient remained relieved of her obstructive hydrocephalus and had recovered nearly normal vision. In 1939 Torkildsen described an alternative method

of shortcircuiting the flow of spinal fluid from one of the lateral ventricles into the cisterna magna by means of a rubber catheter. After the standard suboccipital craniectomy and the discovery of an inoperable obstructing lesion, this procedure is carried out by placing one end of a catheter in the posterior horn of one of the lateral ventricles through an occipital burr hole and then passing the other under the galea and scalp so that it can be fixed in the cisterna magna.

Either method is capable of establishing lasting drainage. Each operation has certain advantages, and both are far superior to older methods, which have never been really satisfactory. These procedures and the reasons for their failure should be briefly mentioned. Suboccipital decompression has rarely relieved the pressure on an obstructed aqueduct sufficiently to permit free drainage, and then for only a brief period. Passage of a catheter through the compressed aqueduct, with a length of buried rubber tubing left in place to keep the channel between the third and fourth ventricles open has occasionally been successful (Dandy, 2).¹ In view of the frequent distortion and obliteration of the aqueduct, the passage of a catheter up into the third ventricle often involves forcing a passage blindly through the surrounding structures of the mesencephalon. According to Dandy (3) the older method of puncturing the corpus callosum to drain the lateral ventricle always failed because the opening in the ventricular roof remains patent for but a short time. The same has been true of attempts to drain the lateral ventricles directly into the subarachnoid space over the convexity of the hemisphere. Even if these openings in the brain substance were to remain open, the arachnoid would become adherent at their edges so that spinal fluid could not enter the general subarachnoid space. Coagulation of the choroid plexus (Putnam), which occasionally permits the destruction of a sufficient amount of the plexus in infants with hugely dilated ventricles, is not satisfactory in adults with less extreme degrees of hydrocephalus.

¹In a subsequent article Dandy (3) stated that "strictures of the aqueduct of Sylvius recur after any attempt to restore the lumen." In Dandy's reported cases he subsequently removed the buried section of catheter. Dr. W. J. Mixer in this hospital has left the tubing in place in a single case with at least partial relief (unpublished data).

From the Neurosurgical Service of the Massachusetts General Hospital.

Fig. 3. Air studies in Case 2. a, left, Encephelogram illustrates normal fourth ventricle with obstruction of the aqueduct, which is outlined by dots. b, Ventriculogram

shows enlargement of lateral and third ventricles. The upper end of the aqueduct ends in ballooning dilatation at tip of arrow (brought out by dotted line).

Figure 2, a photograph taken postmortem in Case 2 illustrates a wide open stoma 7 weeks after operation. In the 3 other adult cases in which postmortem examinations were performed the stoma was found to be patent and draining successfully in every instance. A subdural fluid collection, as reported by Dandy in his cases, was seen in a single case of infantile hydrocephalus which is not included in this report, but postmortem examination in the 4 cases here described showed that the spinal fluid was confined to the subarachnoid space and was being effectively absorbed.

Our 11 patients suffered from a variety of conditions ranging from apparently benign obstructions of the Sylvian aqueduct to tumors which arose in the region of the third ventricle, brainstem, and cerebellum (Table I). Of these patients 2 have regained useful vision and are alive and well $2\frac{1}{2}$ years to 15 months after operation (Cases 1 and 9). When last heard from these patients were leading normal lives. The most dramatic result was obtained in the first case.

CASE. Mrs. L. S., aged 30 years, had noticed headaches of increasing severity for three years, and in addition rapid loss of vision over a period of 15 months. Examination on admission showed papilledema of 3 diopters, left retinal hemorrhages, and visual acuity reduced to $20/400$ in the right eye and $20/50$ in the left. The neurological examination was normal. As her spinal fluid pressure was below 200 , pneumoencephalogram was performed and showed clear-cut block of the Sylvian aqueduct just above the fourth ventricle (Fig. 3a). A subsequent encephelogram demonstrated marked dilatation of the lateral and third ventricles, with the aqueduct ending in ballooning dilatation 1 centimeter below the pineal body (Fig. 3b). The long history of headaches and the appearance of the block in the x-ray film strongly suggested benign occlu-

sion of the Sylvian aqueduct. Third ventriculostomy by the suprachiasmatic route was therefore carried out on March 1, 1938. The following is an excerpt from the operative note:

After the usual right frontal craniotomy the dura along the floor of the anterior fossa was elevated and opened off back toward the sphenoid ridge. Tapping of the ventricle relieved the tension of the brain and thereafter it was easy to free up the entire optic chiasm and both optic nerves, as well as to expose the region just above the chiasm and the lateral carotid, middle, and anterior cerebral arteries on the right. With these landmarks all in view, the bony thinned-out shell of the third ventricle just above the chiasm was perforated. A large amount of ventricular fluid escaped. This opening, as enlarged until it was nearly 1 centimeter across. Finally puncture was made in the posterior floor of the third ventricle. It could be felt beneath the tip of the silver probe cut through the posterior wall and entered the interpeduncular cistern. This part of the operation was bloodless. After adequate hemostasis had been established the dura, bone and scalp were resutured in the usual manner.

The patient made most satisfactory recovery and was discharged after 9 days. During this short period her papilledema had receded to striking degree. Within a period of 5 weeks the patient's visual acuity had recovered to $20/70$ in the right eye and $20/5$ in the left. When seen 4 months later visual acuity remained the same. Both optic discs are flat, but marked trophic persistence on the right. Since then, with the patient has reported on no more occasions by letter, stating that she remains free from headaches, has retained useful vision, and is able to lead normal life. The last report as received on November 14, 1940, 1 year and 8 months after her operation.

Four other patients (Cases 4, 7, 8, and 1) were relieved of hydrocephalus. The first of these were unfortunately operated upon too late to save vision. The third died months later in another hospital of bronchopneumonia, and permission to perform a postmortem could not be obtained. The fourth was the only patient in

Fig 4. Technique of Torkildsen ventriculostomy. The inserts illustrate incisions for the suboccipital craniotomy and insertion of catheter in right lateral ventricle (upper left), the trocar for inserting catheter into the ventricle (upper center). Technique of inserting the catheter. Note the thread that has been tied to the catheter to serve as depth marker and to suture to the galea after the trocar

has been withdrawn (upper right). In the main drawing the stitches are shown which are used for anchoring the lower end of the catheter into the cisterna magna and closing the dura. The arachnoid covering the cisterna has not been sketched, but it is important to include this membrane in the sutures in addition, as the description in the text indicates.

failed to show a reduction in intracranial pressure to a normal level. This was due to a large cavernous hemangioma of her left temporoparietal lobe with extension to the basal ganglia. This tumor not only compressed the aqueduct, but raised the intracranial pressure by its great size. A subsequent partial removal of the mass resulted in the patient's death.

Three patients died as a result of operation, making a case mortality of 27 per cent. These included Case 3 in which patient died of pulmonary embolism, and Cases 5 and 6, in which patients developed complicating postoperative hematomas. Death in Cases 2 and 10 was due to compression of vital centers by the tumor, which continued after the obstructing hydrocephalus had been relieved.

Before Torkildsen reported his ingenious operation we drained the obstructed ventricular system

through the anterior route in cases in which a previous posterior exploration or strong clinical and ventriculographic evidence pointed to an inoperable lesion as the cause of the obstruction. But the bitter experience of missing a cystic hemangioblastoma of the cerebellum in Case 2, in which air injection had indicated a tumor of the midbrain, taught us the risk of relying on ventriculographic evidence for the exclusion of an operable lesion in the posterior fossa.

CASE 2. H S., a 6 year old girl, entered the Children's Service after 10 months of headache and vomiting. She had a bilateral sixth nerve paresis, with spastic weakness of her left leg and arm, as well as of the right leg. At first there was only slight papilledema and no nystagmus or signs of cerebellar pathology. Her pupils reacted very sluggishly both to light and accommodation. Flat skull plates showed increased convolitional markings and widened cranial sutures. On the supposition that these symptoms and signs were due to occlusion of the fourth ventricle by a medulloblastoma, a trial of radiation therapy was in

Fig. 5. Postoperative ventriculogram. Its catheter in position.

stiffened and continued for several weeks, but without any improvement.

The girl, as first seen in consultation by one of us (J. C. W.) at the end of this period. She was then semi-stuporous and in too poor condition for a satisfactory neurological examination. One additional observation of interest, which had not been recorded previously, was that upward movement of her eyes appeared to be limited. A ventriculogram was performed and suggested obstruction of the aqueduct near its upper end, "probably due to tumor which lies mainly at the floor of the aqueduct. As believed that tumor in this situation is inoperable, anterior drainage of the third ventricle was performed through a suprachiasmatic approach on August 3, 1935.

Following operation the patient made a surprisingly good recovery and regained the use of her extremities. The signs of increased intracranial pressure disappeared. When the left ventricle was tapped only 50 cubic centimeters of cerebrospinal fluid escaped at normal pressure, whereas before operation the pressure had been over 400 millimeters. But in spite of the relief of the obstructive hydrocephalus she began to develop signs of cerebellar pathology a month later. With evidence of compression of the vital medullary centers, which caused her death fifteen weeks.

Postmortem examination revealed satisfactory relief of hydrocephalus, with the open stoma through the lamina tennalis above the optic chiasm (Fig. 6). Comparison of the preoperative ventriculogram with the postoperative measurements of the ventricles showed a striking reduction in their size. The cause of death was bilateral bronchopneumonia, secondary to compression of the brain stem by cystic hemangioblastoma of the left cerebellar hemisphere. The primary lesion could have been easily attacked and the compression of the aqueduct relieved if a suboccipital exploration had been made soon after her admission.

As a result of this unfortunate experience we have reached the conclusion that ventriculostomy through the anterior wall of the third ventricle should not be performed unless both clinical and laboratory evidence point unquestionably to the

presence of an obstructing lesion which is inoperable because of its situation, or unless this diagnosis has been established at a previous exploration. Under these circumstances, as in Cases 1, 3, 4, 5, 6, 10 and 11 this form of ventriculostomy could seem to be the most satisfactory operation. Had we known of Torkildsen's approach sooner we should have preferred this in Cases 2, 7 and 9, in which the cause of obstruction was uncertain. This valuable procedure, as will be seen, permits the surgeon to explore the posterior fossa as a preliminary to permanent ventricular drainage. In Case 8 with otitic hydrocephalus an occipital operation could not have been considered in any case because of the presence of a septic mastoid wound.

DRAINAGE OF LATERAL VENTRICLE INTO THE CISTERNA MAGNA—TORKILDSEN OPERATION

A standard suboccipital craniectomy is performed through a midline longitudinal incision in the scalp and upper neck. If the cervical fascia is cross cut just below its insertion in the occipital bone there is no need to make a cross-bow incision in the scalp. After scraping the muscles off the bone low enough to expose the arch of the atlas vertebra, this portion of the occiput and the arch of the atlas are resected away. The dura is next opened crucially. In opening the arachnoid over the cisterna magna it is important to incise it longitudinally and then to use every precaution to preserve the two lateral flaps of arachnoid and dura intact, so that the cistern can be reconstructed in the subsequent closure. The surgeon is then in a position to make a thorough exploration of the posterior fossa and also to test the patency of the aqueduct by determining whether it will admit the passage of a fine soft rubber catheter. In the face of an inoperable high tumor or an occlusion of the aqueduct Torkildsen recommended the following procedure. If an occipital burr hole for decompression of the ventricular system has not been made as a preliminary to opening the tense cerebellar dura, a small trephine opening is made in the occipital bone 3 centimeters above the tentorium and directly over the posterior horn of the right lateral ventricle. The position of the posterior horn is first ascertained by puncture. As the ventricular needle is withdrawn a trocar 4 millimeters in diameter is inserted along its tract. When the stylet is pulled out the metal sleeve serves as a guide for insertion of a No. 8 soft rubber catheter. Before this is slipped into the ventricle an extra eye should be cut close to its tip and a silk suture tied around it to serve as a depth marker and for later suture

Following the metastatic diagnosis in this patient, no further patients have been subjected to therapeutic trial of radiation for medulloblastoma, without previous verification by exploration and biopsy.

of the catheter to the galea at its point of exit from the skull. The catheter tip should be thrust 2 to 3 centimeters into the ventricular cavity. The metal sleeve is then removed and the rubber tube sutured firmly to the galea. When this maneuver has been completed, a tunnel is made between the galea and cranium to permit the passage of the catheter from the small separate incision over the trephine opening to the larger midoccipital one. This can be carried out without difficulty by separating the tissues with a large curved hemostat, seizing the lower end of the catheter, and drawing it back through the resultant tunnel. The catheter is now cut off so that its lower end just reaches the cisterna magna (Fig. 4). This is then reconstructed as accurately as possible over the tube by suturing together the two lateral flaps which were saved for this purpose. Burying and securely fixing the end of the catheter beneath the arachnoid is perhaps the most important part of the operation. It can be accomplished best if the surgeon plans his incision carefully as he opens the dura and arachnoid overlying the cistern. In reconstructing these membranes we have passed fine silk stitches through the dura, arachnoid, and outer layer of catheter, and then out through the same layers in reverse order. Both incisions are then closed in layers with silk sutures. When the dressing is applied a checkrein of adhesive tape is incorporated in it from vertex to shoulder blades to prevent forward flexion of the head for the first few days. Figure 5 illustrates the position of the catheter in the first patient, with the ventricles outlined by air injection 12 days after operation.

The three adult patients who have been submitted to this operation in the advanced stage of hydrocephalus with intense headache, vomiting, high grade papilledema, and increasing somnolence have recovered and remained relieved of their obstructive symptoms for periods ranging from 5 to 18 months. The striking improvement which may follow the institution of permanent drainage by a buried catheter is summarized in Table II and in the history of the following patient.

CASE 13. T. K., a 21 year old man, entered the hospital with a 10 months' history of headache, chiefly in the occipital region. Three weeks before admission his headaches had become increasingly severe and incapacitating. For several days before entry he held his head rigid because of the pain, but he was able to walk without apparent unsteadiness. He complained of episodes of nausea but had not vomited. Recently his family had noticed increasing irritability and slowing of his speech, but no definite change in his mentality.

On examination the patient was sluggish mentally and held his neck in slight extension. His breathing was slow and labored. Ophthalmoscopic examination revealed 4 to 5

diopters of choking, with small striate hemorrhages above both discs and a small hemorrhage in the right macula. His vision was very poor, particularly in the right eye, and the rough field determinations were normal, but his condition was too critical to permit accurate examination. There were no outstanding cerebellar signs and no nystagmus, but a suggestive impairment in upward deviation of the eyes. Otherwise the cranial nerves were normal. This was also true of the spinal reflexes as well as of the motor and sensory examinations.

Because of threatened respiratory paralysis, occipital burr holes were made on the evening of his admission. The next morning a cerebellar exploration was performed with Torikildsen drainage of his right lateral ventricle into the cisterna magna. The operative note reads as follows:

"Under general anesthesia a ventricular needle was inserted through the right sided burr hole made last night. The ventricle was easily entered and proved to be large, containing over 75 cubic centimeters of fluid under high pressure (200+). This having been ascertained, the safest course appeared to be a cerebellar exploration and palliative drainage of the hydrocephalus, if no operable tumor were found. The patient was therefore placed in cerebellar position, and through a midline incision the occipital muscles were cross-cut and a broad area of occiput was exposed. This was removed together with the arch of the atlas. After the dura had been opened, the cerebellar hemispheres were seen to be symmetrical and the vermis not widened. Only a small pressure cone was present. The cerebellum was not tense because the needle had been left in the lateral ventricle. After separation of the cerebellar tonsils one could look upward into a normal appearing fourth ventricle. A No. 10 catheter slipped up the aqueduct met a definite obstruction at a point 4 to 5 centimeters above the lower end of the fourth ventricle. When the anesthetist gave jugular compression, no fluid escaped from above, suggesting that the site of obstruction lay in the upper portion of the aqueduct in the region of the quadrigeminal plate, and that it would be inaccessible to surgery from below. Therefore the palliative procedure described by Torikildsen was carried out. The tip of a No. 8 catheter was buried in the posterior horn of the ventricle and the tube was then passed underneath the scalp from the incision over the burr hole to the median cerebellar incision. Its other end was carefully sutured beneath the arachnoid and dura in the cisterna magna. We were very careful to ascertain that spinal fluid flowed freely out of the tube before closing the arachnoid and dura. The neck muscles were then carefully resutured to the occiput and to each other in the midline. This procedure was tolerated well, blood pressure remaining at a normal level throughout."

The patient was in good condition after operation, and on the fourth day his lumbar and intraventricular pressure readings were normal. Phenolsulfonphthalein was injected into the ventricle and 10 per cent recovered in the urine in the next 2 hours. A ventriculogram carried out 3 weeks later showed free drainage from the previously obstructed ventricles, as all the gas was found distributed over the subarachnoid space. Five days afterward a second ventriculogram was undertaken, 1 cubic centimeter of phenolsulfonphthalein was injected first, followed by 90 cubic centimeters of oxygen. The injection displaced spinal fluid from the ventricles and this was drained through a second needle in the lumbar subarachnoid space. The rapid appearance of dye in the fluid recovered in the lumbar region and a previous pressure reading of 105 millimeters established the patency of the artificial drainage system. The subsequent x-ray films showed a symmetrical dilatation of the lateral and third ventricles without any visible filling of the aqueduct. Beginning on the twenty-fifth postoperative

TABLE 1 RESULTS OF THIRD VENTRICULOSTOMY THROUGH THE LAMINA TERMINALIS IN THE TREATMENT OF OBSTRUCTIVE HYDROCEPHALUS

Case	Symptoms	Neurological examination	Optic discs	Vision	Cerebral spinal fluid pressure	X-ray	Drainage	Operation	End result
Ka Lambert Age 20	Increased attacks of vomiting and headache at times, 3 yrs	Intelligence within normal limits	Peripapillary D	O.D. 0.5 I.D. 1 only light perception	70	Destruction of aqueduct with internal hydrocephalus	Obstruction of aqueduct	3rd ventriculostomy	Little normal life for 15 years. Recovered vision in 1 yr, 10 yrs
Am Hills Age 40	Headache and vomiting 9-10 times	Normal speech, intelligence L.V. 1 nerve paralysis	Peripapillary D	Completely normal	40	Obstruction aqueduct, upper and lower	Hydrocephalus, enlargement of the cerebellum (posterior)	3rd ventriculostomy	Relief of hydrocephalus, no enlargement of cerebellum, no enlargement of lateral ventricles
Ka Vickers Age 40	Headache and vomiting, loss of consciousness with rigidity of neck, rigidity of trunk, rigidity of extremities, loss of consciousness, loss of consciousness	Dullness, clumsy with arms, weakness, loss of consciousness, loss of consciousness, loss of consciousness, loss of consciousness	Normal D	Intelligence 10	40	Partial obstruction of aqueduct, loss of consciousness, loss of consciousness, loss of consciousness, loss of consciousness	Posterior (posterior)	3rd ventriculostomy	Relief from headache, improvement in consciousness, improvement in rigidity, improvement in rigidity, improvement in rigidity, improvement in rigidity

day x-ray therapy was given in six four doses. At the time of discharge the last traces of papilledema were disappearing, and vision had recovered to 20/40 and 20/20. There was still impairment of upward gaze, suggestive of mid-brain lesion.

Since discharge the patient has made most satisfactory recovery. At his last follow-up examination on September 26, 1940 (10 months after operation) he appeared to be in excellent health. He complained of no headaches or other symptoms of intracranial pathology. If he stood up suddenly there was momentary unsteadiness, but other wise his gait and movements were normal. He had recovered full upward movement of the eyes and showed no neurological abnormality. Except for slight pallor of the right optic disc, ophthalmoscopic examination showed normal conditions. The patient felt that his vision had fully recovered. He planned to return to his previous occupation as a clerk.

SELECTION OF OPERATION

Both methods of draining the obstructed ventricles here reported appear to accomplish their purpose in an effective and lasting manner. The obstructed cerebrospinal fluid is drained into the large arachnoid cisterns, whence it can be distributed to the absorbing areas in the subarachnoid space in a normal fashion. It is obvious that these procedures can be effective only in the obstructive form of hydrocephalus. In the communicating type, in which basilar cisterns or absorbing areas in the cranial subarachnoid space are obliterated, nothing can be accomplished by these operations. This variety of hydrocephalus can be diagnosed by the history of a recent meningococcal infection. It can be verified by the fact that phenolsulfonphthalein injected into the ventricles appears in the lumbar region, although very little is absorbed in the blood stream and eliminated by the kidneys (Dandy and Blackfan, 6).

In choosing the most suitable method of ventricular drainage it is of great importance to localize the obstructing lesion as accurately as possible. In most cases this can be done by clinical and x-ray examination. In Case 1 a block in the sylvian aqueduct was clearly visible after the combined injection of oxygen into the lateral ventricles and lumbar subarachnoid space (Fig. 3). Pneumoencephalography however is often too dangerous to use in patients with elevated intra-cranial pressure. Ventriculography alone usually gives accurate localization in the presence of a tumor in the third ventricle, but may be misleading in infratentorial lesions. This led to an unfortunate result in the second patient, in whom an upward projection of the mesencephalon was mistaken for a midbrain tumor whereas actually the deformity was caused by an operable cystic tumor of the cerebellum. We recommend drainage of the third ventricle only if previous exploration or

the combined evidence of clinical and radiological examination has demonstrated beyond a doubt that the obstructive lesion cannot be attacked directly.

The method of Torikildsen has the strategic advantage of permitting preliminary exploration of the posterior fossa before the institution of palliative drainage of the obstructed cerebrospinal fluid. It is surprising that the presence of a rubber catheter embedded in the cisterna magna is not followed by rapid closure of its open end by arachnoid adhesions. Fortunately this has not proved to be the case as shown by Torikildsen's experience and the long-standing relief in the 3 cases here reported. Although unlikely it is still possible for occlusion to occur or for the rubber to deteriorate after a number of years. Should either of these complications take place, drainage can again be re-established through the supratentorial route. This operation does not involve the insertion of a foreign body and appears to be a more physiological procedure in cases in which, in the posterior portion of the third ventricle or below there is an obstruction which cannot be corrected surgically.

SUMMARY AND CONCLUSIONS

1. Two effective operations have been reported in recent years for the drainage of the ventricular system in cases of obstructive hydrocephalus in adults.

2. The first method consists of perforating the thin, bulging anterior wall of the third ventricle (lamina terminalis) and establishing drainage of the obstructed cerebrospinal fluid into the chiasmatic cistern. In certain cases it is also possible to perforate the floor of the dilated third ventricle posteriorly thereby creating a second drainage channel into the interpeduncular cistern. From our experience we believe that this additional opening is not essential and should not be attempted unless it can be carried out with ease and safety.

3. In the second method which is carried out only after exploration of the posterior fossa has revealed an inoperable lesion, the cerebrospinal fluid is short-circuited past the obstruction in the aqueduct, third or fourth ventricle by means of a buried rubber catheter. The tip of the catheter is inserted through an occipital trephine opening and fixed in the posterior horn of the lateral ventricle. The rubber tube is then passed beneath the scalp to the cerebellar incision and its lower end is buried in the cisterna magna.

4. As the latter operation permits a preliminary exploration of the posterior fossa, it is the more

effective method of dealing with cases of hydrocephalus in which the cause of obstruction may be an operable tumor situated in the cerebellum or fourth ventricle, or an arachnoiditis which blocks the outflow of cerebrospinal fluid. On the other hand, when the obstruction is known to be inoperable and is situated in the posterior portion of the third ventricle or caudal to this point, anterior drainage through the lamina terminalis is the more satisfactory operation.

5 Both methods are capable of producing a long lasting channel for escape of the obstructed cerebrospinal fluid into the subarachnoid space, with relief from the symptoms of elevated intracranial pressure and its dangers to life and vision. This is exemplified by the case histories of 14 patients whom we have treated in this way. The hydrocephalus has been relieved in all. Life has been preserved in 7 and useful vision has been established in 5, 4 have been able to return to work and remain in good condition after intervals of 18 months to 3 years.

ADDENDUM

Since this manuscript was sent in for publication we have received reports from Dr F D Ingraham and Dr W J German of 3 other patients with obstructive hydrocephalus on whom the Torkildsen operation was performed. These cases are so instructive that brief résumés of their histories have been added. We wish to thank these surgeons for their kindness in permitting us to include this interesting material.

1 A girl of 5 entered the Children's Hospital with a story of high intracranial pressure and cerebellar signs. In the course of study it was shown that she had a block at the upper end of the aqueduct. Dr Ingraham reports that he "explored this region by dividing the tentorium and exposed a medulloblastoma. A small piece of tissue only was removed for section, and when the diagnosis was verified she was given a course of radiation. The division of the tentorium and the effects of the radiation were not sufficient to relieve the block, and a Torkildsen procedure was carried out. This patient died 14 months after this last operation. There is no question but that the bypass restored her to comparatively good health and gave her a much more satisfactory survival period than she would have had otherwise. We have now had an opportunity to study the brain and the local examination was extremely interesting. The tube was quite unchanged in appearance. It was patent and there was a reservoir at the lower end into which fluid was obviously passing from the ventricle. Death was presumably due to local increase in size of the tumor which made it impossible for fluid to pass from the cisterna magna into the subarachnoid area over the cortex."

2 Dr Ingraham's second patient was a boy 6 years of age with a typical midline cerebellar syndrome and obstructive hydrocephalus. "At operation he was found to have a

block in the aqueduct, although no tumor was exposed, and it was taken to be a congenital abnormality. The Torkildsen procedure was carried out and he was watched for 3 months. His pressure remained normal during that time, and after a short trial of clamping the tube through a small incision we thought that he might have stabilized and removed the tube. In a very short time his pressure was elevated again and the tube was replaced. For several months he had a rather large collection of fluid in the region of his suboccipital decompression. This has returned to normal contour and his pressure has stayed within normal limits. The total period of observation in this patient is also 14 months. He is now symptom free, goes to school, and takes part in ordinary activities."

3 Dr German has written us about a patient in the New Haven Hospital on whom he performed a Torkildsen operation for stenosis of the sylvian aqueduct. This girl did not maintain lasting relief of her internal hydrocephalus so that 5 weeks later it became necessary to re-explore her posterior fossa. The lower end of the catheter opened into a large smooth walled cavity in the occipital region which was completely walled off from the cisterna magna. After further exploration of the upper end of the fourth ventricle Dr German discovered a stenotic band at the lower end of the aqueduct, which he was able to cut and thereby released the obstruction.

This is the only case to our knowledge followed by secondary closure of the catheter. As we have pointed out in the article, such a complication can be corrected if necessary by a subsequent third ventriculostomy. It is better to run the risk of an occasional late closure of the tube than to lose the opportunity for a direct attack on an operable lesion through failure to explore the posterior fossa, as is the case when third ventriculostomy is done as a primary procedure.

FINE ALLOY STEEL WIRE SUTURES

An Experimental and Clinical Study

Y. K. WU M.B. Ch.B., and H. C. PAI, M.B. Ch.B.,
Peking, China

OF the many factors influencing the healing of surgical wounds, the reaction accompanying the use of different suture materials has been studied most extensively. The ideal suture, however, is yet to be found, although catgut and silk have been employed most frequently. The superiority of the latter over the former in most circumstances has been adequately demonstrated by many experimental and clinical observations (6, 7, 9, 10, 12, 13, 14, 15). However, in the presence of infection, the silk suture may act as a nidus for the organisms and prolong the period of healing. For this reason, many surgeons still prefer catgut and even the most ardent advocates of silk (6, 7, 14) warn against its use in infected wounds. In 1934, Babcock (1) proposed the use of fine alloy steel wire as a permanent suture material. Because of its fine caliber, smooth surface, nonpermeability, and chemically stable nature, he claimed that this material was satisfactory for use in both aseptic and infected wounds. This author's subsequent experience seemed to substantiate these claims (2, 3, 4). Also, Kaufman, Johnson, and Lesser, in an analysis of 56 cases of hernioplasty, found the incidence of wound infection to be much lower in the group of cases in which wire sutures were employed than in the groups closed with catgut or silk. Bunnell reported favorable results from the use of wire sutures in the repair of tendons. Preston demonstrated experimentally in rats that wounds sutured with fine wire had a greater tensile strength than that of similar wounds sutured with catgut or silk. In view of these encouraging reports we were led to investigate further the behavior of fine alloy steel wire when employed as a suture material in both animal and human tissues and to attempt to estimate its relative merits in comparison with the more commonly used materials.

EXPERIMENTAL STUDY

Four groups of experiments were conducted in order to compare the tissue reaction produced by alloy steel wire sutures with that produced by

silk or catgut sutures in both aseptic and infected wounds. The wire employed in all of the experiments was size 35. It is a whitish pliable hair-like string having a diameter of 0.0007 of an inch and a tensile strength of 25 pounds (1).

Group 1: Tissue Reaction in Aseptic Wounds

Procedure. Incisions 5 centimeters in length were made in the abdominal wall of dogs deeply enough to expose the anterior sheath of the rectus muscle. Three interrupted sutures of the alloy steel wire were applied through the rectus sheath and a part of the muscle in each wound. Three similar sutures of either silk or catgut were placed in the same wound for the purpose of comparison and control. All of the sutures were applied with fine curved needles of the same size. The wounds were reopened at different intervals after the operation and gross changes around the sutures were noted. This was followed by the excision of blocks of fascia and muscle bearing the sutures, for the purpose of microscopical study. The specimens were fixed in a 10 per cent solution of formalin. The wire sutures were removed after the fixation and sections were made through the fascia and the muscle at the places through which the sutures had passed. All sections were stained with hematoxylin and eosin. The control sutures consisted of silk, both No. C (medium silk) and No. A (fine silk) grades; plain catgut, No. 1 and No. 00; and chromic catgut, No. 1 and No. 00. Observations were made at periods varying from 24 hours to 20 days after original application of sutures. Altogether 21 wounds were studied.

Gross examination. *Wire sutures.* In recent wounds, no inflammatory reaction was observed in the tissues around the sutures. However, most of the sutures appeared tighter than at the time of the original application, causing a slight constriction of the fascia. In the wounds more than 1 week old, the wire was covered by a thin layer of fibrous tissue. Staining or necrosis of tissues around sutures was not noticed and the color and luster of the wire remained practically unchanged.

Silk sutures. Slight to moderate edema and necrosis were observed in wounds 2 and 5 days

From the Departments of Surgery and Pathology, Peking Union Medical College, Peking, China.

old Although of less intensity than those observed around the catgut sutures, these changes, in contrast to those around the wires, were very distinct. After 9 days, the sutures were found to be buried in a rather heavy layer of fibrous tissue. In a few specimens, a small amount of cloudy fluid was found around the sutures as long as 20 days after they had been applied.

Catgut sutures Moderate edema, slight necrosis, and a small amount of turbid exudate were invariably observed around the catgut sutures in wounds less than 5 days old. The reaction around the plain catgut was especially marked. That around the No. 00 sutures was slightly less than that around the No. 1 sutures of both plain and chromic gut. Plain catgut began to show evidence of disintegration on the fourth or fifth day and usually had totally disappeared after 7 days. The chromic catgut sutures were fairly well preserved for the first 2 weeks, after 20 days they were found to have disappeared.

Microscopic examination. Wire sutures Sections of tissue from 24 hour to 3 day old wounds showed the presence around each suture of a thin layer of hyalinized material probably formed as a result of compression of the tissues by the sutures. In the surrounding tissue, there was slight leucocytic infiltration, some edema, and occasionally a small amount of fibrinous exudate. In the 4 day wound there was slight proliferation of fibroblasts and infiltration with lymphocytes and plasma cells in the neighborhood of the sutures. In the wounds more than 7 days old, the number of fibroblasts decreased while the amount of intercellular collagen fibrils increased. Granulation tissue was not observed. Aside from some atrophy of the muscle fibers in immediate neighborhood, there was no other evidence of damage to tissues.

Silk sutures The tissue reaction to the No. A silk was less than that to the No. C silk sutures. However, the difference was not marked, and they are described together. In wounds less than 5 days old the sutures were surrounded by some necrotic tissue infiltrated by a large number of leucocytes. In the non-necrotic tissue in the neighborhood there was moderate leucocytic, and occasionally also fibrinous, exudate. After 5 days the acute inflammatory reaction began to subside. However, among the filaments of the sutures there usually were some leucocytes. At the same time there was fibroblastic proliferation and infiltration of lymphocytes, plasma cells, and large mononuclear phagocytes. The latter often were crowded together in close apposition to the sutures, later foreign body giant cells frequently were seen. In tissues from wounds 13 to 20 days

old, the acute inflammatory reaction usually had largely disappeared, but a few leucocytes remained among filaments of the sutures or in their immediate neighborhood. The sutures were surrounded by a broad zone of newly formed fibrous tissue.

Catgut sutures The plain and the chromic sutures of the same size caused a very similar reaction, but the finer sutures (No. 00) produced relatively less reaction than the heavier ones (No. 1). A description of the microscopic findings of the tissues sutured by No. 1 chromic catgut will suffice. A very intense and extensive acute inflammatory reaction was observed around the sutures in wounds from 1 to 5 days old. The reaction was not limited to the immediate neighborhood of the sutures but involved the adjacent tissues for some distance. There was heavy leucocytic infiltration, marked fibrinous exudation, congestion, and edema. The leucocytic infiltration was so intense around the sutures that small abscesses were often formed. The tissues surrounding the sutures, including the muscles, usually showed necrosis. In the 4 day specimens, granulation tissue began to appear and reached the maximum amount on the seventh to the ninth day. The sutures at this time still were surrounded by a zone of leucocytic exudate. The granulation tissue was infiltrated by many leucocytes, lymphocytes, plasma cells, and numerous large phagocytes containing many nuclear fragments and fatty droplets. There was no tendency for these phagocytes to form foreign body giant cells. In the specimens from wounds more than 9 to 13 days old, there was considerable fibrosis in the granulation tissue, but marked leucocytic infiltration still was observed in the immediate neighborhood of the partially absorbed catgut sutures. The majority of the sutures began to show fragmentation and penetration by leucocytes as early as the fourth or fifth day. A few appeared to be intact up to the thirteenth day.

Summary Table I summarizes the tissue reaction around the different kinds of sutures as observed at varying intervals after they had been placed in position. It will be seen that the wire sutures caused very slight initial acute inflammatory reaction followed by a slight amount of fibrosis without the formation of actual granulation tissue. The silk sutures produced a more acute inflammatory reaction, some granulation tissue and much fibrosis. The catgut sutures caused a very severe acute inflammatory reaction in the early wounds with frequent formation of minute abscesses. This was followed by extensive granulation and fibrosis. These changes are illustrated in Figures 1 to 4.

Group II Tissue Reaction in Infected Wounds

Procedure. The procedure employed was essentially similar to that in Group I, except that the sheath and fibers of the rectus muscle were divided down to the peritoneum and 1 cubic centimeter of a 24 hour broth culture of *Bacillus coli* was introduced into the wound before the sutures were applied. Wire sutures were employed to reapproximate the rectus sheath throughout one half of the incision for controls No. C silk was used to close the other half of the rectus sheath in 4 wounds and in another 4 wounds No. 1 chromic catgut was employed. Observations were made, and tissues were removed for microscopic examinations on the 2nd, 5th, 8th, and 14th days after the application of the sutures.

Gross examination. All wounds became swollen after 48 hours and showed signs of mild suppuration during the next few days. By the end of one week, most of the wounds appeared to have healed externally. At the time of removal of the specimens, however from 2 to 3 cubic centimeters of pus was evacuated from each of the and 5 day wounds and from the 8 day wound containing catgut. In 3 other wounds, 1 of 8 days containing silk and the 2 others of 14 days containing silk and catgut, respectively, there was no free fluid. There was surprisingly little reaction around the wire sutures in any of the wounds even when free pus was present. Around the catgut, extensive necrosis and fibrinous exudate were noticed. In the 14 day specimen, the sutures were

partially dissolved and came out on slight manipulation. However in the 8 day specimen, most of the catgut sutures still were intact although surrounded by purulent exudate. An intermediate reaction was seen around the silk sutures. In the 8 and 14 day specimens the wounds were healed and clean. Immediately around the silk, a small amount of mucogelatinous exudate remained.

Microscopic examination. *Wire sutures.* The sutures in the 2 day old wound were surrounded by a small amount of leucocytic and fibrinous exudate which was continuous with a similar exudate present throughout the wound. In the 5 day wound the acute reaction around the sutures had subsided and fibroblasts had appeared, although signs of acute inflammation still were present in the tissues farther removed from the sutures. In the 8 day specimen the sutures were surrounded by a thin layer of hyaline material. The acute inflammatory reaction in the surrounding tissues also had subsided and granulation tissue infiltrated by lymphocytes and plasma cells had appeared. In the 14 day wound the sutures were surrounded by an inner thin layer of hyaline material and an outer fairly broad zone of fibrous tissue.

Silk sutures. In the 2 day wound, the sutures were infiltrated by leucocytes and surrounded by a moderate amount of serofibrinous and leucocytic exudate. In the 5 day wound, the acute inflammatory reaction in the surrounding tissues had become much more extensive. At 8 days,

Fig 1 Tissue reaction to sutures, 2 days after application $\times 40$ a, Wire (represented by an oval empty space in all illustrations) Note absence of cellular infiltration around suture and only slight inflammatory reaction in surrounding tissues b, No C silk Suture is partially encircled by purulent exudate with moderate inflammatory reaction in surrounding tissues c, No 1 chromic catgut Very extensive acute inflammatory cellular infiltration

Fig 2 Tissue reaction to sutures, 5 days after application $\times 40$ a, Wire There are a moderate number of fibroblasts around the suture Note the marked constriction on the tissue in this section b, No C silk The acute inflammatory reaction in the surrounding tissues is subsiding, granulation tissue has formed in the surrounding tissues c, No 1 chromic catgut Very extensive purulent exudate still is present

the sutures were surrounded by granulation tissue which was infiltrated chiefly by leucocytes and to a less extent by lymphocytes, plasma cells, and large mononuclear phagocytic cells. In the 14 day specimen extensive granulation tissue had formed and there was very active proliferation of fibroblasts, especially around the sutures. Large numbers of leucocytes still were present, some

of them were among the filaments of silk. A large number of mononuclear phagocytes were scattered among other cells in the granulation tissue, but they did not encroach upon the sutures.

Catgut sutures Sutures in the 2 day wound were surrounded by a large amount of fibrino-purulent exudate which became even more abundant after 5 days. Fragmentation of the

where in the wound, the silk and catgut sutures, on the other hand, were surrounded by many more leucocytes. In the wounds of 8 and 14 days (Fig 5 and 6), the difference was even more striking. The inflammatory reaction around the wire sutures had subsided, but the silk and catgut sutures still were bathed by purulent exudate.

Group III Peritoneal Reaction

Procedure Rectus incisions 4 inches in length were made on each side of the midline of the abdominal wall of 4 dogs. The peritoneum was incised along the entire length of each incision, but the structures within the peritoneal cavity were not disturbed. The peritoneum was reapproximated with a continuous suture of No. 1 chromic catgut in the upper half and a continuous suture of No. 35 alloy steel wire in the lower half of the incision on the right side. On the left, a continuous wire suture was employed in the upper half and a continuous suture of No. C silk in the lower half of the incision. The rectus sheath and the skin were closed with interrupted sutures of No. A silk on both sides. These animals were sacrificed 7, 11, 14, and 21 days later, respectively.

Results In the first 3 dogs, identical pictures were observed. In the areas sutured with catgut or silk, the whole line of the peritoneal incision was covered by adherent omentum while the portions sutured with wire were entirely free and were represented by linear scars (Fig 7). In the fourth dog, the segment sutured with silk was covered heavily by omentum while the other three areas all had healed without adhesions.

Group IV Healing of Infected Wounds

Procedure The method used in this series of experiments was similar to that employed by Shambaugh and Dunphy (13) in their study of the relative merits of silk and catgut sutures in infected wounds, except that fine alloy steel wire was used with silk and catgut for controls.

A rectus incision down to but not through the peritoneum was made on each side of the midline of the abdominal wall of a dog. To each of the wounds, 1 cubic centimeter of a saline suspension of dog's feces was applied in order to produce marked infection. On the right side the rectus sheath was closed by means of interrupted sutures of No. 35 alloy steel wire. The same material was used for ligating bleeding points in the wound. On the left side an equal number of interrupted sutures of No. 1 chromic catgut was employed. No. 1 plain catgut was used for ligating bleeders. The skin was closed with interrupted sutures of fine silk on both sides. This procedure was carried out in 2 dogs. In another 2 dogs, a similar procedure was employed except that in the left rectus wound, No. C silk was used for the anterior rectus sheath and No. A silk for ligating bleeding vessels. All the wounds were examined daily. Alternate skin stitches were removed 3 days, and the remaining stitches 5 days, after the operation. When an accumulation of pus was noticed, the wound margins were separated with a clamp and gentle pressure was applied to the rest of the wound in order to evacuate the discharge. No other treatment was given except the application of a sterile dry dressing after each examination.

Results All wounds were swollen and frankly suppurating 48 hours after the operation. The initial swelling was most marked in those wounds closed with catgut, least in those closed with wire, and intermediate in those in which silk had been employed. The amount of pus evacuated on the first separation of the wound corresponded closely to the degree of the swelling. The wounds closed with wire progressed rapidly toward healing as soon as the pus was evacuated. By the end of the first week, all discharge had ceased. All four wounds sutured with wire healed completely by the end of 2 weeks. None of the wire sutures was discharged. The two wounds closed with catgut showed the largest amount of discharge.

Fig. 3. Tissue reaction to sutures, 9 days after application. $\times 40$. a, Wire. The inflammatory reaction has entirely subsided, slight fibrosis is seen. b, No. C silk. The suture is surrounded by organizing granulation tissue. c, No. chronic catgut. Fragmentation of the suture has occurred. There still is much leukocytic infiltration and granulation tissue.

Fig. 4. Tissue reaction to sutures, thirteen days after application. $\times 40$. a, Wire. Very little fibrosis is seen. b, No. Catgut. Moderate fibrosis. c, No. chronic catgut. The suture still is surrounded by granulation tissue. Fibrosis is taking place at the periphery. Note the infiltration of leukocytes between the fragments of the suture.

sutures with penetration of leucocytes was observed in the 5 day specimen. In the 8 day specimen the sutures appeared as fragments in the center of an abscess lined by a wall of granulation tissue heavily infiltrated by leucocytes. Only a few lymphocytes, plasma cells, and large mononuclear phagocytic cells were present. By 14th day picture still was the same, except that there was more fibrosis of the granulation tissue.

Summary The tissue reaction to wire silk, and catgut sutures in infected wounds is summarized in Table II. In the 2 and 5 day specimens, there was a diffuse inflammatory reaction throughout the whole wound as a result of the infection. However the reaction in the immediate neighborhood of the sutures varied according to the suture material. The cellular infiltration around the wires was no heavier than that else-

Extensive granulation tissue and purulent exudate are present.

ever they drained for a longer period of time. After 2 weeks, while the wounds closed with wire in the same dogs had healed completely, discharging sinus persisted in each of the wounds closed with silk (Fig 9). In one dog the sinus closed spontaneously 16 days later; in the other it persisted for 43 days without sign of healing. When the sinus tract was laid open, it was found t

be lined by soft gelatinous granulation tissue within which were buried five silk sutures. These were removed, and the wound healed 10 days later.

CLINICAL STUDY

During the past year, one of us (Y K W) has used fine alloy steel wire as the main suture material for the closure of 40 abdominal incisions. In each instance the peritoneum was closed with a continuous suture of No. 1 chromic catgut, the anterior rectus sheath was reapproximated with figure-of-eight sutures of No. 35 alloy steel wire, the subcutaneous layer was closed with interrupted sutures of the same material (in thin individuals this layer of sutures was omitted), and the skin was brought together with interrupted sutures of No. 1 silk. Hemostasis was secured largely by electrocoagulation.

All of the incisions, with three exceptions, were of rectus or paramedian type, varying from 10 to 20 centimeters in length. More than two-thirds of the operations involved the opening of the lumen of the gastrointestinal tract. There were 14 gastrostomies, 1 total and 2 partial gastrectomies, 7 instances of resection and anastomosis of the small or large intestine, 6 operations for intestinal obstruction (enterostomy, colostomy, division of peritoneal adhesions, etc.), 2 instances of simple exploratory celiotomy, and 8 other operations upon the spleen, liver, and biliary tract. Thirty-seven of the 40 wounds were clinically aseptic while 3 were made through contaminated fields. These two groups are considered separately.

Group I Clean Wounds

Two patients of this group did not recover from the operation. However, at the time of death, 1 and 5 days, respectively, after the operation, the wounds showed no sign of infection. The wounds in the other 35 patients healed *per primam*. It was our general impression that the induration along the line of the incision during the course of healing of these wounds was definitely less than that in wounds closed with either catgut or silk. No patient had undue pain or other complaint that could be attributed to the presence of the wires. Even in thin individuals, when the sutures could be palpated through the skin, there was no tenderness. In no instance did a suture work out through the skin during the period (a few weeks to a few months) this group of patients was under observation. Four patients with carcinoma of the esophagus died in the hospital from 1 to 8 months after gastrostomy. Postmortem examination showed that all the wire sutures were well preserved and without evidence of gross change.

Fig. 7. Pentoneal surface of abdominal wall of dog showing parallel rectus incisions closed with continuous sutures of different material: A and D, No. 35 alloy steel wire; B, No. 1 silk; C, No. 1 chromic catgut. Specimen excised 2 weeks after operation. Note the smooth healing in the sections sutured with wire and the heavy omental adhesions in the sections sutured with catgut or silk.

Microscopic examination of the tissues around the sutures revealed a minimal amount of fibrosis.

The largest group in this series of cases was that of gastrostomy of the Janeway type for patients suffering from carcinoma of the esophagus. It was with the idea of reducing an excessively high incidence of postoperative wound infection in this group of debilitated patients that we first began to employ wire sutures for the closure of the abdominal wound. During the last 4 years, 62 operations of this nature have been performed by 8 surgeons in the Peiping Union Medical College Hospital. The incidence of infection and disruption of the wounds, grouped according to the suture material used for the closure of the abdominal wall, is shown in Table III.

It is not justifiable to draw any conclusion concerning the small group of cases in which catgut was used, although the fact that infection and disruption occurred in 2 of the 3 cases suggests that catgut is an unsuitable suture material. In comparing the incidence of complications in the 2 other groups, there was a marked lowering of the rate of infection in the group in which wire was used, but the incidence of disruption was

Fig. 5. Tissue reaction to sutures in infected wounds, 8 days after application. $\times 40$. a, Wire. The inflammatory reaction has subsided and fibrosis has begun. b, No. C silk. ever they drained for a longer period of time. After 2 weeks, while the wounds closed with wire in the same dogs had healed completely a discharging sinus persisted in each of the wounds closed with silk (Fig. 9). In one dog the sinus closed spontaneously 16 days later. In the other it persisted for 43 days without sign of healing. When the sinus tract was laid open, it was found to

TABLE III—COMPLICATIONS OF ABDOMINAL INCISIONS IN JANEWAY GASTROSTOMIES FOR CARCINOMA OF THE ESOPHAGUS

Type of suture material	Cases	Infection		Disruption	
		Number	Percentage	Number	Percentage
Catgut	3	2	66 7 ± 22 5	2	66 7 ± 22 5
Silk	36	9	25 0 ± 4 9	1	2 8 ± 1 9
Wire	23	2	8 7 ± 4 1	2	8 7 ± 4 1
Whole series	62	13	21 0 ± 3 5	5	8 1 ± 2 3

tion His wound became infected due to necrosis of the gastrostomy stump and ruptured on the seventh postoperative day The other patient developed a tracheoesophageal fistula at the site of the carcinoma Violent attacks of coughing followed and the wound broke open on the eighth postoperative day

Since factors other than the type of suture material employed must be considered in the problem of the healing of wounds, it may be worthwhile to compare the incidence of complications following the same type of operation performed by the same operator The personal series of Janeway gastrostomies for carcinoma of the esophagus of one of us (Y K W) consists of 22 operations One of 2 wounds closed by catgut became infected and disruption followed, 2 of 7 wounds closed by silk became infected, with disruption in 1, but all of 13 wounds closed by wire healed without complication

Group II Contaminated Wounds

In 3 of the 40 cases in this series, the wounds were contaminated grossly at the time of operation

CASE 1 In an infant 6 months of age, excision of a congenital umbilical fistula due to a patent omphalomesenteric duct was carried out The incision was made through the macerated skin around the umbilicus The wound was closed with wire sutures and healed without sign of infection

CASE 2 In performing a splenectomy for cirrhosis of the liver, it became necessary to extend the incision through an infected area of the abdominal wall On the sixth day, a localized abscess was found beneath the skin at the site of the original incision Following separation of the edges of the wound in this area the infection subsided promptly Complete healing occurred within 2 weeks

CASE 3 During an operation for the repair of a fecal fistula, the wound was contaminated by the unexpected opening of a peritoneal abscess The main portion of the wound was closed with wire sutures, but the end overlying the abscess was left open for drainage In spite of the poor general condition and marked nutritional disturbance of the patient, the sutured portion of the wound healed promptly and the whole wound closed by the 28th postoperative day It was not necessary to remove any of the wire sutures during the healing of the wound, nor were any of these sutures extruded spontaneously

Fig 10 Diagram showing the correct, a, left, and incorrect, b, method of twisting the wire sutures

In several other instances in this clinic contaminated wounds closed with fine alloy steel wire (by other surgeons) showed a similar favorable response The wounds either healed without clinical evidence of infection or only mild infection developed Even in the presence of frank suppuration, the wire sutures remained in position and became covered by healthy granulations within a relatively short period of time

FIXATION OF WIRE SUTURES BY TWISTING

The chief objection to the use of alloy steel wire sutures is the difficulty of handling and tying the wire In order to simplify this procedure, we merely twisted the ends of the wire three complete turns instead of attempting to form the usual type of knot Sometimes the twisted ends (which were 2 to 3 mm in length) were turned downward with a hemostat By this method, we not only could anchor the individual sutures in a much shorter period of time, but also could regulate the tension of the sutures more accurately than by the classical formation of knots The last mentioned point constitutes an important reason for the use of this method of fixation of the wire sutures It is imperative, however, that the two ends of the wire be twisted equally so that they will lock and maintain their position (Fig 10)

This method of fixing the wire sutures was used in most of the experimental animals None of the sutures was found to have become untwisted or to have shifted from its original site at the time at which the specimen was removed The method also was employed in 10 patients All wounds healed without complication In 7 instances in which subsequent roentgenological examination was carried out, the wire sutures were found to be in satisfactory position

EVALUATION OF STUDY

We believe that this study has demonstrated a less severe reaction of the body tissues to fine alloy steel wire sutures than to either catgut or silk, under both septic and aseptic conditions The evidence presented by the illustrations alone (Figs 1 to 9) is so striking that further comment scarcely seems to be necessary However, we may summarize our observations in the following manner Fine alloy steel wire sutures initiate only a very mild inflammatory reaction in the surrounding tissues Even this reaction

Fig. 8. Abdominal wounds infected with saline suspension of dogs' feces. The rectus sheath has been closed with No. 35 alloy steel wire on the right side and No. 1 chromic catgut on the left side. a, 3 days after operation. Wire wound, slightly swollen. Less than cubic centimeters of pus evacuated. Catgut wound, markedly swollen 30 cubic centimeters of pus evacuated. b, 5 days after operation. Wire wound, healing; discharge scanty. Catgut wound, still swollen with moderate amount of pus. c, 7 days after operation. Wire wound, almost completely healed. Catgut wound, still discharging pus. Whole incision is uninfected. Complete healing, 14 days later.

Fig. 9. Abdominal wounds infected with saline suspension of dogs' feces. The rectus sheath has been closed with No. 35 alloy steel wire on the right side and No. 1 silk on the left side. a, 3 days after operation. Wire wound, moderately swollen, 5 cubic centimeters of pus evacuated. Silk wound, markedly swollen 20 cubic centimeters of pus evacuated. b, 5 days after operation. Wire wound, healing, except for superficial necrosis; discharge scanty. Silk wound, moderately swollen with purulent discharge. c, 7 days after operation. Wire wound, completely healed. Silk wound, upper two-thirds of wound uninfected. Wound drained for 43 days and healed only after it was reopened and some silk sutures removed.

distinctly higher in this group than in the group in which the wound was closed with silk. However, in the 3 instances in which disruption of the

wound occurred following closure by wire, the patients suffered from severe attacks of coughing. One developed bronchopneumonia after opera-

PERITONEAL ASPIRATION IN THE DIAGNOSIS OF STRANGULATED BOWEL

FREDERICK C HILL, M D , F A C S , BERNARD J O'LOUGHLIN, B S , and
MAURICE STONER, M S , Omaha, Nebraska

DURING the course of some experiments on dogs in which a loop of strangulated bowel was placed in a rubber bag, we observed that within a few hours the bag began to fill with an exudate, profuse in amount, which had a cherry-red or pink color. This fluid appeared before the loop ruptured and the redness of its color gradually increased until after the loop ruptured, when it of course, took on the appearance of the contents of strangulated bowel. We showed in the previous investigations (3) that this fluid is toxic when injected intravenously into another animal. In order to confirm the presence of this exudate, in the absence of the rubber bag although it has been previously mentioned by Scott and Wangenstein who studied the fluid found in various types of obstructions in dogs, we produced strangulated loops of bowel 4 inches long in another series of dogs. We found that fluid which was exactly similar to the fluid present in the bag formed in the abdominal cavity in these animals. The fluid contains blood, and the erythrocytes are present in approximately the concentration which is produced when one drop of blood is placed in one cubic centimeter of water.

Richardson in 1920 called attention to this rusty, blood-stained fluid in cases of strangulation of the bowel and suggested that the appearance of such peritoneal fluid might aid in the diagnosis of intestinal obstruction after the abdomen had been opened. In a series of 135 cases of intestinal obstruction he found 21 in which there were strangulation of the bowel and this typical fluid. There were also a few cases in which, although there was interference with the mesenteric circulation, it was definitely stated that there was no rusty fluid. Richardson believed that these cases came to operation before the fluid had time to form. In some cases of simple obstruction he noted that clear, straw-colored fluid may be present. Scott and Wangenstein in their studies on various types of obstructions in dogs found that when the mesenteric veins were ligated, 50 to 250 cubic centimeters of hemorrhagic fluid having low pro-

tein content and little if any odor, developed. In those dogs with arterial or with both venous and arterial obstruction, 100 to 500 cubic centimeters of dark bloody foul-smelling fluid with high protein content was present.

Because of the striking character of this fluid and its positively diagnostic nature when present, we were led to perform a series of experiments on dogs in which we attempted to aspirate fluid from the abdominal cavity at various intervals after strangulation obstruction had been produced. The procedures followed were the same on all animals. Under intratracheal ether anesthesia and with the usual sterile precautions, a midline incision was made, and a segment of jejunum 12 inches long and 1 foot below the ligament of Treitz was ligated with cotton tape. The vessels of the mesentery were included in the ligature but the tape was not pulled tightly enough to obstruct the arteries. The abdomen was then closed in layers by the usual method. The peritoneal cavity was aspirated, a lumbar puncture needle being used at 1, 2, 4, and 6 hour intervals after the operation.

As shown in the accompanying table, in 2 dogs fluid obtained 1 hour after operation contained in one instance many red blood cells and white blood cells, and in the other, white blood cells only. At 2 hours, in 3 of 4 animals, fluid was obtained which under the microscope showed many red blood cells and white blood cells. Culture of this fluid showed no growth in one, and showed chain streptococci and gram negative short rods in another. At 4 hours, aspiration of the abdominal cavity of all 4 animals revealed typical reddish fluid which was diagnostic of strangulation and culture from this time on was always positive for bacteria which we did not identify. At 6 hours, in all animals, the same type of fluid was obtained. The animals died during the night, and in all cases the loop was found at necropsy to be ruptured. Two additional dogs were operated on and obstructed loops 2 feet in length were produced. These dogs were sacrificed at 14 to 16 hours, and the loops of bowel were found not to be ruptured. In each case about 40 cubic centimeters of the typical fluid was found in the pe-

From the Department of Surgery Creighton University School of Medicine.

seems more likely to be due to trauma incidental to the passage of the needle and the suture than to the continued presence of the wire. This reaction soon subsides and is replaced by the healing process. In the instance of silk, the initial reaction is distinctly more marked and the subsequent fibrosis also is relatively more extensive. In infected wounds leucocytes and granulation tissue not only appear around the sutures but also infiltrate between the filaments of the silk. Therefore until the sutures are removed the infection is likely to persist. As McFadden Jackson and Ochsner have pointed out, this is the chief reason why the presence of silk sutures may seriously delay the healing of infected wounds. Catgut sutures produce the most extensive early as well as delayed type of inflammatory reaction. As a matter of fact, a majority of all catgut sutures actually are bathed in minute aseptic abscesses until their filaments are largely or completely absorbed. These changes certainly predispose toward infection of the wound. Furthermore, in the presence of infection, catgut sutures either are dissolved or sloughed off before solid healing of the wound has had time to occur. This leads to disruption of the wound in certain instances.

From these observations, it may be suggested that catgut is not a suitable suture material for the closure of either aseptic or infected wounds. Silk is a generally satisfactory material for clean wounds, but is to be avoided in the presence of infection. Fine alloy steel wire is preferable to either catgut or silk for both clean and infected wounds. We believe this type of wire to be especially suitable for the closure of abdominal wounds after operations in which there is a potential chance of contamination, as in extensive resections or anastomoses of gastrointestinal tract. In presence of frank infection, fine alloy steel wire is undoubtedly the suture material of choice.

In using wire sutures, the general principles laid down by Halsted for the use of silk should be rigidly observed, with special emphasis on the avoidance of tension. In our experience No. 35 alloy steel wire is satisfactory for suturing both the aponeurosis and the subcutaneous fascia. Thicker and stronger wire is probably unnecessary. The wire can be sterilized by boiling or autoclaving. It may be sterilized repeatedly without loss of strength. The low cost of the wire (2) is another distinct advantage.

SUMMARY AND CONCLUSIONS

1. The behavior of fine alloy steel wire sutures was studied in dogs, catgut and silk sutures being

used as controls. Gross and microscopic observations were made in both aseptic and infected wounds. It was found that wire sutures produced the least amount of tissue reaction and promoted the most rapid healing of the wounds.

2. Clinical experience with forty abdominal incisions closed by fine alloy steel wire sutures showed that all clean wounds healed *per primam*. Reduction in the incidence of wound infection was especially remarkable in a group of jejuney gastrostomies established for patients suffering from carcinoma of the esophagus. In 3 instances of contaminated wounds, primary healing occurred in 1 and only localized infection developed in the others, both of which healed without disruption and without extrusion of the suture material.

3. On the basis of these observations, more extensive use of fine alloy steel wire sutures is recommended, especially in wounds potentially or obviously contaminated. We realize, however, that the final evaluation of this type of suture can be determined only by careful observation of the immediate as well as the late results in a much larger number of cases.

4. In using wire sutures, the rules laid down by Halsted for the use of silk should be followed closely. Special emphasis should be placed on the avoidance of tension when the sutures are tied. The fine caliber and the unyielding character of the wire tend to cause it to constrict and to cut through the tissues if this precaution is not observed.

5. In order to facilitate the tying of wire sutures and the regulation of the tension exerted by them on the tissues within their grasp, we recommend elimination of the customary knot and fixation of these sutures by simple twisting of the ends of the wire for three complete turns.

PERITONEAL ASPIRATION IN THE DIAGNOSIS OF STRANGULATED BOWEL

FREDERICK C HILL, M D , F A C S , BERNARD J O'LOUGHLIN, B S , and
MAURICE STONER, M S , Omaha, Nebraska

DURING the course of some experiments on dogs in which a loop of strangulated bowel was placed in a rubber bag, we observed that within a few hours the bag began to fill with an exudate, profuse in amount, which had a cherry-red or pink color. This fluid appeared before the loop ruptured and the redness of its color gradually increased until after the loop ruptured, when it of course, took on the appearance of the contents of strangulated bowel. We showed in the previous investigations (3) that this fluid is toxic when injected intravenously into another animal. In order to confirm the presence of this exudate, in the absence of the rubber bag although it has been previously mentioned by Scott and Wangenstein who studied the fluid found in various types of obstructions in dogs, we produced strangulated loops of bowel 4 inches long in another series of dogs. We found that fluid which was exactly similar to the fluid present in the bag formed in the abdominal cavity in these animals. The fluid contains blood, and the erythrocytes are present in approximately the concentration which is produced when one drop of blood is placed in one cubic centimeter of water.

Richardson in 1920 called attention to this rusty, blood-stained fluid in cases of strangulation of the bowel and suggested that the appearance of such peritoneal fluid might aid in the diagnosis of intestinal obstruction after the abdomen had been opened. In a series of 135 cases of intestinal obstruction he found 21 in which there were strangulation of the bowel and this typical fluid. There were also a few cases in which, although there was interference with the mesenteric circulation, it was definitely stated that there was no rusty fluid. Richardson believed that these cases came to operation before the fluid had time to form. In some cases of simple obstruction he noted that clear, straw-colored fluid may be present. Scott and Wangenstein in their studies on various types of obstructions in dogs found that when the mesenteric veins were ligated, 50 to 250 cubic centimeters of hemorrhagic fluid having low pro-

tein content and little if any odor, developed. In those dogs with arterial or with both venous and arterial obstruction, 100 to 500 cubic centimeters of dark bloody foul-smelling fluid with high protein content was present.

Because of the striking character of this fluid and its positively diagnostic nature when present, we were led to perform a series of experiments on dogs in which we attempted to aspirate fluid from the abdominal cavity at various intervals after a strangulation obstruction had been produced. The procedures followed were the same on all animals. Under intratracheal ether anesthesia, and with the usual sterile precautions, a midline incision was made, and a segment of jejunum 4 inches long and 1 foot below the ligament of Treitz was ligated with cotton tape. The vessels of the mesentery were included in the ligature but the tape was not pulled tightly enough to obstruct the arteries. The abdomen was then closed in layers by the usual method. The peritoneal cavity was aspirated, a lumbar puncture needle being used at 1, 2, 4, and 6 hour intervals after the operation.

As shown in the accompanying table, in 2 dogs fluid obtained 1 hour after operation contained in one instance many red blood cells and white blood cells, and in the other, white blood cells only. At 2 hours, in 3 of 4 animals, fluid was obtained which under the microscope showed many red blood cells and white blood cells. Culture of this fluid showed no growth in one, and short chain streptococci and gram negative short rods in another. At 4 hours, aspiration of the abdominal cavity of all 4 animals revealed typical reddish fluid which was diagnostic of strangulation, and culture from this time on was always positive for bacteria which we did not identify. At 6 hours, in all animals, the same type of fluid was obtained. The animals died during the night, and in all cases the loop was found at necropsy to be ruptured. Two additional dogs were operated on and obstructed loops 2 feet in length were produced. These dogs were sacrificed at 14 to 18 hours, and the loops of bowel were found not to be ruptured. In each case about 40 cubic centimeters of the typical fluid was found in the peri-

FOUR INCH STRANGULATED LOOPS

Dog no. Weight in lbs.	Hours after obstruction	Amount of aspirated fluid	Color of fluid	Smear of exudate	Culture of exudate	Autopsy findings
347		drop	Clear	Few RBC; many WBC	Negative	Loop ruptured and part near the puncture dead present. Loop black Omentum and intestine loosely together with ad- hesions
		drops	Empty	Many RBC, WBC and large fat globules	Aerobic: few short chains streptococci Slight acid Anaerobic: few gram negative short rods

tonal cavity. Samples of this fluid were removed for culture and smear and the findings agreed with those of the fourth and sixth hour punctures, but the quantity of organisms and cellular matter was much greater. In no instance, as far as we were able to determine, was the bowel punctured by the aspirating needle. As control experiments, a simple obstruction was produced by a tape in 2 other dogs and 18 hours later no fluid was found on opening the peritoneal cavity.

Denzer (12) and Neuhauf and Cohen have previously reported on the value of peritoneal aspiration in the clinical diagnosis of various types of peritonitis, and all emphasize the safety of the procedure and point out the difficulty of puncturing the intestine. The bowel moves away from the point of the needle and it takes considerable force to enter into its lumen. If the bowel should happen to be adherent to the peritoneal wall at the site of the puncture, the intestine probably would be penetrated, but under these conditions

the puncture would be of little importance since there would be no leakage into the peritoneal cavity. The site chosen for puncture is probably of little importance. If a mass is present it should be avoided and the needle, of course, should be inserted high enough above the symphysis to miss the bladder. We have performed aspiration on one patient with acute intestinal obstruction and considerable distention, and no puncture of the intestine occurred. It is not difficult to tell when the needle enters the peritoneal cavity and with ordinary care we believe that the procedure is safe. It sometimes requires aspiration for as long as a minute to obtain the fluid, according to Denzer and if no leakage of air into the peritoneal cavity is permitted before suction is applied, it is easier to aspirate the fluid. We are not reviewing the value of this procedure in the diagnosis of other intra-abdominal conditions, because Horsley and the authors previously quoted have already done so.

CONCLUSION

In the experimental animal, strangulated bowel can be diagnosed within 4 hours after onset by the aspiration of characteristic fluid from the abdominal cavity

EDEMA OF THE PANCREAS

HANS L. POPPER, M D, and H. NECHELES, M D, Ph D, Chicago, Illinois

EDEMA of the pancreas has been described first by Archibald, and several years later as a clinical entity, by Zoepffel. The cause and nature of the edema is still obscure. Some authors believe it is not related to pancreatitis but is a disease by itself, due to inflammation or to retention of the pancreatic secretion in the ducts. Other authors consider it to be the precursor or a mild manifestation of pancreatitis or pancreatic necrosis. The appearance of an edematous pancreas gives the impression that one is not dealing with an edema as seen in inflammation or congestion of other organs. This is probably the reason why this process has not been called simply edema of the pancreas, but usually is called "glassy edema of the pancreas." Cutting into such an edematous organ reveals that the edematous appearance is due to a gelatinous imbibition of the tissues, which do not contain much free fluid, no free fluid is oozing from the cut surface of the edematous pancreas as seen in edema of other organs. A small quantity of free fluid accumulates, however, under the capsule and in the interlobular spaces of the pancreas, which can be aspirated for chemical determinations. In cases of edema of the pancreas in dogs as well as in humans just as in cases of acute pancreatitis, exudate is found in the peritoneal cavity containing a high concentration of pancreatic enzymes. (2) These enzymes are undoubtedly derived from the pancreas. In animal experiments direct observation of the initial stages of pancreatic edema shows the exudation of fluid from the surface of the gland. These findings suggest that in edema of the pancreas (as in pancreatitis) a diffusion of pancreatic juice occurs first into the pancreatic

parenchyma and later into the peritoneal cavity. In recently published animal experiments it has been shown that this subcapsular and interstitial edema fluid contains large amounts of pancreatic enzymes. (2) It was concluded from this finding that edema of the pancreas is due to an imbibition of the pancreatic and peripancreatic tissues with pancreatic juice.

It is well known that ligation of the main or of all of the pancreatic ducts in dogs usually is not followed by edema of the pancreas. Injection of bile, duodenal juice, or other substances into one pancreatic duct followed by ligation of the duct, however, leads regularly to an edema of the organ within a few minutes. In order to find out whether edema of the pancreas could be produced by more or less physiological means, that is, by stimulating the gland while one or more ducts were obstructed, the following experiments were performed.

In 4 dogs, the main pancreatic duct and, in 2 dogs, the main and one accessory duct were ligated. The pancreas was observed 5 to 60 minutes after this procedure, and no edema was observed. At that time 3 to 4 milligrams per kilogram of body weight of secretin were injected intravenously, and within a few minutes (3 to 5) edema of the pancreas began to appear, spreading rapidly over the entire organ. Fifteen to 30 minutes later the entire pancreas had been involved extensively. The edema subsisted for a number of hours, then it subsided gradually and had disappeared almost completely 4 hours after injection. At that time a few fat necroses could be observed in the peripancreatic tissue of a few dogs. Some subcapsular edema fluid was aspirated at the height of the edema and was found to contain large amounts of amylase and lipase, similar to edema fluid obtained following injection of bile into the pancreas. (2)

From the Department of Gastro-Intestinal Research, Michael Reese Hospital, Chicago. Aided by the A. B. Kuppenheimer Fund. A preliminary report read at the meeting of the American Physiological Society, April 1941.

Peritoneal exudate was usually found as early as 15 minutes after administration of the secretin and likewise showed a high concentration of amylase and lipase. The increase of blood enzymes which is regularly observed after ligation of pancreatic ducts occurred much later than the finding of enzyme containing fluid in the peritoneal cavity.

In a control experiment the pancreatic duct was not ligated and secretin was injected intravenously. No change in the pancreas occurred within 1 hour, when the main pancreatic duct was ligated and the same amount of secretin was injected as before. A few minutes later an extensive edema of the pancreas developed.

In 4 dogs the main pancreatic duct was ligated and drugs which are known to stimulate pancreatic secretion like mecholyl and eserine or pilocarpine were injected. This procedure was not followed by edema of the pancreas. In 1 dog .05 cubic centimeter of its own duodenal juice was injected into the main pancreatic duct, which was then ligated. Ten minutes later no change was noted. After that pilocarpine was injected subcutaneously and a few minutes later extensive edema of the pancreas developed.

Finally in 1 dog both pancreatic ducts were ligated and one tenth normal hydrochloric acid solution was infused into the duodenum at the rate of 40 drops per minute. Fifteen minutes after the beginning of the infusion of hydrochloric acid into the duodenum a marked edema of the pancreas developed in the central portion of the organ. The edema was not as extensive, however as the one observed following injection of secretin. It is apparent that in this experiment the edema of the pancreas was produced by secretin liberated by the hydrochloric acid from the mucous membrane of the small intestine.

These experiments demonstrate that in the presence of complete or partial obstruction to the outflow of pancreatic juice an edema of the pancreas may be produced in dogs by injection of secretin or by the physiological mechanism of liberation of secretin in the small intestines, after acid gastric juice has entered the latter. The secretory effect of secretin is much greater than

that of the vagotropic drugs applied, namely pilocarpine and mecholyl and eserine. It is possible that the production of edema of the pancreas in case of retention of secretion is dependent on the amount of secretion retained, in other words, on the degree of pressure developed within the ducts. However the different composition of pancreatic juice secreted to secretin and to vagotropic drugs must be considered also. The experiment in which injection of a very small amount of duodenal juice into a pancreatic duct was not followed by edema but in which, following injection of pilocarpine edema developed points to an activation and potentiation of pancreatic enzymes within the duct system of the pancreas.

Our observations on dogs may be applied to man. It is a well known clinical observation that attacks of pancreatitis usually begin after a copious meal. If in such a person the outflow of pancreatic juice would be obstructed more or less completely even for a very short period of time, the secretin mechanism activated by the hydrochloric acid from the stomach as well as by products of digestion would be sufficient to produce an acute edema of the pancreas.

SUMMARY

Pancreatic edema is produced by the diffusion of pancreatic juice into the pancreatic parenchyma and peripancreatic tissues. Extensive edema of the pancreas could be produced in animal experiments by ligation of a pancreatic duct and subsequent stimulation of pancreatic secretion by secretin, or by activation of the secretin mechanism by infusion of dilute hydrochloric acid into the duodenum. Under the same conditions stimulation of pancreatic secretion by vagotropic drugs did not lead to formation of edema.

These experiences may be applied to man in whom, under conditions of complete or incomplete obstruction of the pancreatic duct, the secretin mechanism activated by a meal may cause edema of the pancreas.

CHANGING CONCEPTS OF THE ACCEPTED TREATMENT FOR ACUTE HEMATOGENOUS OSTEOMYELITIS

TEN years ago in most medical schools acute hematogenous osteomyelitis was considered an excellent example of acute infectious surgical disease. The necessity of making an extremely early diagnosis was emphasized, successful treatment was thought to be contingent entirely upon this. The treatment, almost the entire treatment, was then based upon drilling into the bone, the intention being to permit the escape of the infection. In 1920, the second edition of one popular textbook of surgery expressed this dominant idea, thus "As soon as the diagnosis is made the bone should be opened. Delay even of a few hours is dangerous."

Acute hematogenous osteomyelitis is not a particularly common disease, a fact which may explain the now seemingly long delay in questioning whether the method of treatment being taught was the best form of manage-

ment even for a decade ago. A real reckoning of the question revealed surprising figures. For example, in the Charity Hospital at New Orleans, from 1930 to 1936, inclusive, there were 112 primary cases of acute hematogenous osteomyelitis, that is, cases in which patients had not been operated upon elsewhere and not recurrent cases. In this group the accepted teaching that drilling the bone was the essential part of treatment was followed, in 84.8 per cent of the cases the initial operation involved opening the bone. Operation was performed in over 71.4 per cent of the cases within 48 hours after patients were admitted to the hospital and in 90 per cent of these the bone was opened. Thus in 64.3 per cent of all the cases the bone was opened within 48 hours after the patient entered the hospital. The surprising mortality for the entire series was 26.2 per cent, and for those operated upon within 48 hours after admission to the hospital, 32.2 per cent. Obviously something was wrong. This and many other analogous reports showed that operation was not accomplishing what surgical teaching maintained it would. From 1927 through 1940, 66 patients with primary acute hematogenous osteomyelitis have been admitted to Charity Hospital. In this group is reflected a much more conservative attitude regarding operation, for 36.4 per cent of the patients were operated upon during the first 48 hours after entrance to hospital but in only 27.3 per cent of the 66 patients was operation involving the opening into a bone done within the first 48 hours after entrance. Only 4 patients died in this group of 66, thus giving a mortality of 6 per cent in stark contrast to the mortality of the previous series.

Even though these figures cover a period in which there was a changing attitude regarding operation early in the presence of acute osteomyelitis, and even though they indicate that the mortality rate fell when fewer operations on the bone were performed in such cases, they do not prove conclusively that operation early in osteomyelitis is deleterious. Operation may not have been the only factor in the improved mortality. Even those of us who are convinced, upon present evidence, that operation is harmful early in the disease are justified to the extent only of keeping an open mind. The improvement in mortality certainly is not due to more operations or to earlier operation. It may be due largely to factors other than operation. The correct answer to the question whether or not operation is of benefit early for acute hematogenous osteomyelitis may change the mortality rate as little as 1 or 2 per cent in a series of one hundred cases, for the reason that much improvement has followed the use of more recent therapeutic measures. During recent years, particularly in the treatment of other surgical conditions, the profession has had an impressive lesson on the dangers of dehydration and changes in the blood chemistry in sick surgical patients, with the result that whether emphasized in case reports or not, patients undoubtedly now receive more careful attention as to maintenance of normal fluid and electrolytic balance. Moreover in recent years the repeated re-emphasis of the necessity of maintaining protein requirements has led to the more frequent administration of transfusions. Immunological benefits have resulted from these transfusions. The basic physiology of the patient is thus kept more nearly normal so that his intrinsic defenses against infection are thereby supported. Moreover extrinsic factors, such as chemotherapy and antitoxin, have been

proved of unquestioned value in the management of the condition and though it seems a simple procedure and its effect almost incredible, absolute immobilization of the affected extremity appears to be remarkably beneficial.

Such acknowledged therapeutic advances must be taken into consideration in evaluating the results of operation in any stage of the disease. The real status of operation—its relative worth in combatting the disease and its comparative value in relation to other measures—is at present, to say the least, controversial. For that reason all suggestive real proof is desirable. Studies should be made of small and of large series of cases not only in relation to the status of operation but also in reference to details in clinical and experimental investigation relating to each therapeutic measure. Chemotherapy and antitoxin likely may prove the most remarkable advances in the management of the disease. Pure controversy will carry little weight in ultimate well founded conclusions. Arguments based on the long accepted concept of the pathogenesis—that the disease begins in the end arteries of the metaphysis that pus under pressure comes to the surface through haversionian canals and raises the periosteum for variable distances causing sequestration of the underlying bone—may be worthless, for that concept may be wrong. Thrombosis of the nutrient artery may be the most important change in the local pathological process responsible for determining the extent of sequestration. Many points about the disease remain unanswered. It is not common and intensive studies must be made to prove the value of operation and the best methods of management. One point seems well assured and that is that operation alone early in the disease is not the powerful life saving measure that surgical texts and the teachings of 50 years ago indicated. Other measures now

seem as important, or more important, than surgery. The value of operation on the bone early in the disease still remains an unsettled question.

HOWARD MAHORNER

ACUTE CHOLECYSTITIS WITH PERFORATION

HOW frequently is perforation a complication of the acutely inflamed gall bladder? This question is not readily answered if one includes all of those cases in which slightly bile stained fluid, or secondary abscesses are added to a lesser number in which, due to perforation, a diffuse biliary peritonitis is observed.

Acute cholecystitis manifests itself in two distinct clinical types. First, the usually observed progressive condition which requires several days to reach its peak of severity, both as to symptoms and extent of pathology, but which responds to conservative treatment and can be safely carried over the "waiting" period, second, the fulminating type, the symptoms of which are of short duration, very severe, and in which gangrene and perforation are early complications. In the former group the inflammatory process is rather slow. Peritoneal reaction follows a permeation of the gall-bladder wall by infection or the extension of inflammation, adhesions to the liver, duodenum, colon, stomach, and omentum follow, and secondary abscesses are encountered. Less frequently, due to fixation of the gall bladder to the stomach, duodenum, or colon, fistulas develop, anastomosing the gall bladder to one of these hollow viscera. In either event, this process has occurred rather slowly and therefore the peritoneum has been secured against an escape of bile. During this period the cystic duct quite likely has been occluded by a stone within, or by the inflammatory process, and bile is no longer flowing

into the gall bladder so that should perforation occur, there is not an abundance of bile to escape from the gall bladder. However during this time the inflammatory process is likely to spread throughout the biliary ducts and through them or the accompanying lymphatics into the pancreas or liver.

It is in this group of cases that the numerous complications, so much to be feared, are so frequently encountered. It also contributes tremendously to both the morbidity and mortality of gall-bladder disease. Since the progress of the pathology in this group of cases can be measured in days, there is no reason why these patients should not be studied very thoroughly. No factor influencing the element of safety should be overlooked. All of the known laboratory tests which may be used to estimate liver and kidney function and damage should be employed. The degree of jaundice, if any, should be estimated and what effect it has had on bleeding and clotting time known.

These tests can be applied very rapidly. During the period of investigation the patient should receive an abundance of glucose intravenously. No sedatives should be administered and the clinician should make abdominal examinations at frequent intervals.

The fulminating type presents quite a different problem, here as in the first group, history of previously existing gall-bladder disease can be obtained in a majority of the cases, but the onset of the present attack is very sudden. Pain in the upper right abdomen is extremely violent, vomiting is frequently severe, muscle rigidity in the upper right quadrant is pronounced and exquisite peritoneal tenderness is indicated by the slightest pressure on the abdominal wall. The patient usually has some elevation of temperature and the blood count is variously affected. Under the influence of intravenous

fluids the patient's general condition appears improved but abdominal examinations reveal the same exquisite peritoneal sensitiveness as when first observed or possibly it has spread and increased. This clinical condition suggests a perforating or perforated gall bladder. It has been observed in 10.83 per cent of cases of acute cholecystitis.

The mortality in this group of cases is dependent almost entirely upon the length of time elapsing after perforation and before operation. It is 16.66 per cent. This may be reduced by earlier operation.

A survey of most of the literature of the past ten years on acute cholecystitis indicates the trend of surgeons of today toward earlier operations for this condition.

The mortality in acute appendicitis was gradually lowered, largely by earlier operation, and the mortality and morbidity of perforated gastric and duodenal ulcers have been greatly reduced by similar efforts.

Likewise in considering acute cholecystitis,

surgeons in general would do well if they realized that early operation will do more to reduce both the morbidity and the mortality in this disease than any other treatment, and that while laboratory tests are of incalculable value they must not supplant careful clinical observations for by this latter test must the diagnosis of peritoneal soiling or threatened soiling be made. It is impossible to differentiate a threatened perforation from one that has recently occurred, except by laparotomy.

A biliary peritonitis is known to be highly toxic and fatal in a short time unless adequately interrupted very soon after it has developed.

These facts support the contention that acute cholecystitis with perforation constitutes an abdominal emergency requiring immediate laparotomy and that the complications of the less rapidly developing cases are of such magnitude that the prevention of them by early operation demands very serious consideration.

AN EXPERIMENTAL STUDY OF URETEROINTESTINAL IMPLANTATION

V The Destiny of the Implanted Ureter

FRANK HINMAN, M D , F A C S , and HENRY M WEYRAUCH, M D , F A C S ,
San Francisco, California

EXPERIMENTAL investigation has yielded abundant proof that the lower portion of the implanted ureter constitutes an area of crucial importance in determining the success or failure of a ureterointestinal anastomosis. At successive stages following implantation of the dog's ureter by various modifications of the submucosal method, the animals either died or were killed and the intraluminal and intramural segments were subjected to a special study. In addition to gross and microscopic examination, the ureters in several specimens were injected with a 20 per cent suspension of India ink in gelatin and the region of the anastomosis was cleared by the Spalteholz-Skarda technique in order to localize areas of constriction or dilatation. These findings were correlated with the changes reflected in the upper urinary tract.

It was observed that healing at the site of the anastomosis takes place either by primary union and early epithelization or, in the presence of infection, by granulation, cicatrization and late epithelization (Table I). Al-

From the Department of Surgery, Division of Urology, University of California Medical School.

Supported by the Christine Breon Fund for Medical Research.

though pure forms of both processes occur, the two are more usually associated in one of an innumerable number of possible relationships.

Immediately following operation the usual traumatic manifestations make their appearance. There is edema of the operative area with an infiltration of lymphocytes and plasma cells. Areas of hemorrhage may be present (Fig 1). A foreign body reaction is observed in the region of the sutures.

If there is no infection or if only a mild degree of infection supervenes, as commonly observed in ureterovesical reimplantation, this reaction rapidly subsides and healing occurs by primary intention (Fig 2). This is usually achieved by the sloughing of the intraluminal segment of the ureter. Only in rare instances is the length of this segment preserved exactly as introduced at operation. Most frequently a variable portion of the end separates so that the new orifice is in the plane of the mucosa of the implanted viscus or is situated on a low papilla.

In the absence of infection, sloughing is caused by anemic necrosis alone. The reaction is admirably demonstrated in a series of experiments in which a hollow catgut cylinder

TABLE I—FORMS OF HEALING FOLLOWING URETERAL IMPLANTATION

I Early traumatic edema causing variable degrees of ureteral obstruction	
Without Infection Healing by primary union Early cystic degeneration	With Infection Infection Acute, subacute to chronic Early obstruction of the ureter Healing by granulation
Healing completed + chronic obstruction Final relief of temporary obstructive	Cicatricization Formation of scar tissue may give rise to late obstructions of the ureter Late epithelialization (The end of the ureter may slough from infectious gangrene)
(The end of the ureter may slough from chronic infection)	

was placed in the lumen of the end of the ureter in an attempt to assure the patency of the anastomosis. Since the cylinders fit snugly in many instances with the occurrence of edema, the blood vessels became obliterated and necrosis from pressure ensued (Fig. 3).

If healing takes place by primary union there is little constriction of the ureter other than that occasioned by the transient operative edema. Free communication as demonstrated by injections of gelatin is illustrated in Figures 4 and 5. In addition to exemplifying the ideal which is striven for in all implantations these models serve for comparison with specimens showing obstruction.

When a severe degree of infection ensues an entirely different picture is presented. Soon after the onset of edema the entire wall of the redundant end of ureter becomes engorged with leucocytes chiefly of the polymorphonuclear strain. The adventitia is invaded first but the process soon spreads through the muscularis the submucosa, and to a lesser degree into the mucosa. The surface of the stump is encased in an inflammatory debris containing conglomerations of bacteria (Fig. 6). The more fulminating the inflammatory reaction, the greater is the tendency to occlude the lumen of the ureter. Granulation tissue makes its appearance and gradually replaces the exudate. New capillaries are formed and, as they grow into the granulations fibroblasts appear (Fig. 6 b). Cicatrization becomes greatest in the adventitia and portions of the muscularis where the muscular fibers are destroyed. As healing progresses the inflammatory process recedes from the acute to the subacute, and finally to the chronic stage. The scar tissue contracts over a period of weeks and months

to produce as a general rule, a permanent structure of the ureter (Fig. 7). Healing is prolonged and epithelialization is delayed.

Though the end of the ureter is first to be invaded its intramural extent and the adjacent parts of the intestine do not escape the inflammatory process. Infection spreads upward along the path of the ureter into the intermuscular planes and submucosa of the intestine. The mucosa itself shows minimal invasion probably because of a natural immunity to the fecal content. Sutures form rallying points for infection, and abscesses are prone to develop about them (Fig. 8). Areas of inflammation outside the ureter do not compress it. Except for constrictions and angulations caused by sutures which are placed improperly obstruction to the ureter is always produced by changes within its own wall.

Fig. The early traumatic manifestations seen in the intraluminal end of the ureter days following uretero-intestinal anastomosis. There are areas of necrosis best seen in the submucosa and diffuse edema with an infiltration of lymphocytes and plasma cells throughout all layers.

The end of the ureter sloughs more frequently in the presence of infection than from anemic necrosis alone. As cellulitis progresses, blood vessels and lymphatics become occluded, infectious gangrene results, and separation occurs at the point where sufficient vascularization ends. The greater part of this slough usually takes place soon after the first week, but it may be delayed for a month or more. Despite its own vulnerability to infection, the intestine gives the appearance of forming a protective covering around the submucosal course of the ureter, for, although it is common for a fulminating ureteritis to extend up to the place where the ureter enters the wall of the intestine, such a generalized infection rarely extends beyond it. The end often sloughs level with the rectal mucosa, but not proximal to this point, except in instances of massive necrosis, as will be described. A cross circulation from the intestine lends added vitality to the ureter soon after the first week.

The effects of these pathological changes

Fig 2 Ureterointestinal orifice following healing by primary union. Note the perfect fusion of the ureteral with the rectal mucosa and the coaptation of the two musculatures. a, Shows a foreign body reaction in the region of a suture.

upon the lumen of the ureter were observed following injection with gelatin. In localizing areas of obstruction, it is important not only to note a diminution in the normal caliber of the lumen but equally valuable to observe substantiating evidence from the effects of back-pressure on the kidney and ureter proximal to an area of suspected narrowing. Taking cognizance of both these features it was discovered that, in acute ureteritis, the lumen of the entire intraluminal segment is usually compressed. Later the very tip of the implanted ureter is the initial and most frequent site for the development of a stricture (Fig 9). If more scar tissue is formed, the area of constriction involves the remainder of the intraluminal portion (Fig 10). It is unusual for the process to advance into the intramural segment although this sometimes occurred after a period of several months (Fig 11).

The question naturally arises as to how obstruction in the end of the ureter may be avoided. We have shown that the reduction of infection in the field of implantation (1) is conducive to the prevention of ureteritis with its attendant stasis and later formation of stricture.

We attempted to evaluate, as another factor, the relative advantages of implanting a long or a short end of ureter at operation. In an experimental series of ureterointestinal anastomoses, an end less than 1 centimeter in length was utilized on one side, while the end

Fig 3 Anemic necrosis of the intraluminal segment of the ureter caused by the pressure of a catgut cylinder, 2 days following ureterointestinal anastomosis. The ureter is seen as only a ghost of its normal structure. The catgut cylinder lies within the lumen.

Fig 4. Ideal ureterovesical communication 5 weeks following bilateral ureterocystostomy. There is no constriction of either ureter. A small papilla remains on the right, long papilla on the left. The kidneys and ureters above are normal.

of the opposite ureter was left 3 centimeters long. Although an accurate statistical analysis of this factor was precluded by the complexity of other considerations, we concluded that the shortest possible end which is technically feasible is the most desirable. Since the intraluminal segment bears the brunt of the inflammatory reaction and is the area most consistently narrowed by acute inflammation as well as by the later formation of stricture, it seems rational to reduce its dimensions to an absolute minimum. Furthermore the exposed surfaces of the adventitia unpro-

ected by mucosa or by the wall of the intestine afford the best possible foothold for the entrance of infection.

We have found that our best results are obtained by dividing the end of the ureter tangentially and carrying a longitudinal incision a short distance beyond. Starting at the most proximal point of the beveled end, the wall is divided longitudinally almost to the level at which it is to emerge from the intestine. This step reduces the possibility of occlusion which, as we have demonstrated, is so likely to occur in a long, redundant end and brings the new orifice close to the protected intramural portion of the ureter. Furthermore it opens a broad expanse of ureteral mucosa to promote fusion with that of the intestine.

In our experience the Coffey No. 3 Higgins method and other operations depending on a transfixion suture for the establishment of an orifice are complicated by a higher incidence of obstruction and ascending infection. There is a tendency for the minute orifice to contract from cicatrization and, in a few instances, complete occlusion has occurred. The temporary period of absolute ureteral obstruction is a serious disadvantage of the Coffey No. 3 procedure. One inherent danger of any method which incorporates a transfixion suture is the possibility that the suture may fail to slough through.

of the opposite ureter was left 3 centimeters long. Although an accurate statistical analysis of this factor was precluded by the complexity of other considerations, we concluded that the shortest possible end which is technically feasible is the most desirable. Since the intraluminal segment bears the brunt of the inflammatory reaction and is the area most consistently narrowed by acute inflammation as well as by the later formation of stricture, it seems rational to reduce its dimensions to an absolute minimum. Furthermore, the exposed surfaces of the adventitia unpro-

tected by mucosa or by the wall of the intestine afford the best possible foothold for the entrance of infection.

We have found that our best results are obtained by dividing the end of the ureter tangentially and carrying a longitudinal incision a short distance beyond. Starting at the most proximal point of the beveled end, the wall is divided longitudinally almost to the level at which it is to emerge from the intestine. This step reduces the possibility of occlusion which, as we have demonstrated, is so likely to occur in a long redundant end and brings the new orifice close to the protected intramural portion of the ureter. Furthermore it opens a broad expanse of ureteral mucosa to promote fusion with that of the intestine.

In our experience the Coffey No. 3 Higgins method and other operations depending on a transfixion suture for the establishment of an orifice are complicated by a higher incidence of obstruction and ascending infection. There is a tendency for the minute orifice to contract from cicatrization and in a few instances, complete occlusion has occurred. The temporary period of absolute ureteral obstruction is a serious disadvantage of the Coffey No. 3 procedure. One inherent danger of any method which incorporates a transfixion suture is the possibility that the suture may fail to slough through.

taken not to denude the ureter too completely preparatory to an anastomosis. Occasionally the blood supply is so completely destroyed that an anemic necrosis of the ureter reaches above the site of implantation. When this occurs leakage is inevitable and peritonitis ensues. Infectious gangrene giving rise to a massive necrosis may produce the same result. The danger of this complication is likewise increased by injury to the blood supply (Figs. 12 and 13).

In some of the operations the peritoneum covering the lower portion of the ureter was dissected with the ureter and used as a cuff

around it in implanting the end into the bowel. This has been recommended as a measure to assure the preservation of an adequate blood supply. At necropsy however we noted no decrease in the incidence of infection and obstruction in the ends of the ureters so treated. Ureteritis and sloughing of the ends occurred as usual with the peritoneum participating in the process.

A pathological characteristic which sometimes plays a part in shaping the final result is the adhesive quality of inflamed surfaces. This is displayed by the specimen illustrated in Figure 14. Two long ends of ureter which

Fig 15 Diagram illustrating how crushing the end of the ureter by a ligature during operation may lead to an adhesive process within the lumen and give rise to partial obstruction, or even to occlusion

of the operation by temporary occlusion of the ureter with a bull-dog clamp. Gentle handling is important in order to minimize trauma with its resultant necrosis and infection.

We have demonstrated that ureteral obstruction and ascending infection following uretero-intestinal anastomosis are attributable to the highly contaminated nature of the contents of the large intestine (1). In this paper we have traced the pathological changes which occur in the implanted ureter and have shown that the end of the implanted ureter is a region of crucial importance as concerns a successful result. Subsequent communications will be devoted first, to the effect of these changes upon the upper urinary tract, especially to the relationship between ascending infection and ureteral obstruction (2) and, secondly to the methods of reducing the infectious changes of the implanted portion so that primary healing of the end of the ureter will occur (3).

SUMMARY

The end of the implanted ureter constitutes an area of crucial importance in determining

the success or failure of a uretero-intestinal anastomosis. The pathological changes which occur in this structure are carefully traced, especially with a view to demonstrating the hazards which accompany damage to the blood supply and the entrance of infection if extending above the site of the anastomosis, either anemic necrosis or infectious gangrene gives rise to fatal peritonitis. A virulent infection in the ureteral stump causes serious damage to the upper urinary tract first by acute ureteritis with its attendant stasis and later by the formation of stricture. The changes in the end of the ureter therefore play a great part in accounting for the morbidity and mortality both early and late which attend the operation.

EXCISION OF THE HEAD OF THE PANCREAS FOR CARCINOMA WITH STUDIES OF ITS BLOOD SUPPLY

HROLFE R ZIEGLER, M D , F R C S (C), Rochester, New York

DURING the past 15 years many advances have been made in the surgical treatment of carcinoma of the ampullary region of the duodenum. By far the greatest number of cases of obstructive jaundice due to this cause have been treated by a palliative type of operation in which the gall bladder or common duct has been anastomosed to the stomach or duodenum. It is remarkable that so few attempts at excision of carcinoma localized to this region have been attempted when one realizes that the first operation of this type was done as long ago as 1900 by Halsted. Up to 1927 Cohen and Colp were able to collect only 59 cases in which local excision of carcinoma of the ampulla was accomplished and, though only a relatively small number of these patients survived the operation more than a few days, there were 4 patients who lived beyond 18 months. This report apparently stimulated many surgeons to do the local excision type of operation, so that by 1935 Whipple, Parsons, and Mullins (16) were able to add 20 reported cases to those collected by Cohen and Colp, and in the same year Hunt and Budd found in the literature a total of 76 cases which had been treated in this manner.

Up to this time the lesion had been excised locally with, in the majority of cases, reimplantation of the bile duct, and in 1932 Walters first suggested that the immediate mortality rate from the operation could be reduced if it were preceded by a cholecystostomy. Whipple, Parsons, and Mullins, in their report in 1935, suggested a wide excision of the adjacent pancreas and duodenum for the first time, thus sacrificing the external secretion of this gland and substituting a gastroenterostomy in place of any attempt to preserve the duodenum. This proposed change was based on the following facts: (1) For many years it had been

realized that the external secretion of the pancreas was not essential to life in animals, and it was thought that one could sacrifice it in man without ill effects. (2) A great many postoperative deaths from local excision of the ampulla were due to leakage of pancreatic secretion around the anastomosis which, of necessity, was formed between the amputated ends of the ducts and the duodenum. (3) Whipple stressed that the operation of wide excision, sacrificing the external secretion of the pancreas, conformed to the main principle of cancer surgery in excising large blocks of tissue wide of the growth. This last consideration is of extreme importance, for many cases will show extension into the wall of the common duct itself or the adjacent pancreas, and there is really no point in attempting to excise these lesions if one does not seriously attempt to remove all cancer tissue.

Since this more radical excision is much more time-consuming and involves more risk of shock to the patient who is already in a precarious position as a result of long-standing complete obstruction of the lower end of the bile duct, and in many cases of the pancreatic ducts, Whipple suggested that the operation be done in two stages. The first stage involved a cholecystgastrostomy and gastroenterostomy followed 4 to 6 weeks later by a wide excision of the lesion, a major portion of the duodenum being sacrificed and the previous gastroenterostomy relied on for re-establishment of the continuity of the gastrointestinal tract (Fig. 1).

Following this momentous contribution to the surgery of this region, numerous reports have appeared in the literature attesting to its sound principles and success. In 1938 Whipple (15) again made an important suggestion when he advocated a further change in the technique of the first stage because the cholecystgastrostomy had been found to possess certain defects. The fundamental principle of

of the operation by temporary occlusion of the ureter with a bull-dog clamp. Gentle handling is important in order to minimize trauma with its resultant necrosis and infection.

We have demonstrated that ureteral obstruction and ascending infection following ureterointestinal anastomosis are attributable to the highly contaminated nature of the contents of the large intestine (1). In this paper we have traced the pathological changes which occur in the implanted ureter and have shown that the end of the implanted ureter is a region of crucial importance as concerns a successful result. Subsequent communications will be devoted first, to the effect of these changes upon the upper urinary tract especially to the relationship between ascending infection and ureteral obstruction (2) and, secondly, to the methods of reducing the infectious changes of the implanted portion so that primary healing of the end of the ureter will occur (3).

SUMMARY

The end of the implanted ureter constitutes an area of crucial importance in determining

the success or failure of a ureterointestinal anastomosis. The pathological changes which occur in this structure are carefully traced, especially with a view to demonstrating the hazards which accompany damage to the blood supply and the entrance of infection if extending above the site of the anastomosis, either anemic necrosis or infectious gangrene gives rise to fatal peritonitis. A virulent infection in the ureteral stump causes serious damage to the upper urinary tract first by acute ureteritis with its attendant stasis and later by the formation of stricture. The changes in the end of the ureter therefore play a great part in accounting for the morbidity and mortality both early and late, which attend the operation.

Fig 4, right. The method of George Crile, Jr, used to excise the head of the pancreas for carcinoma (Courtesy, *Am J Surg*, 1940, 47 91)

Since Whipple's report, the use of vitamin K has disposed of the hazard of uncontrollable bleeding in patients of this type who are deeply jaundiced, and we believe it is quite possible, in patients who are otherwise in good condition, to accomplish this whole surgical procedure in one stage. In fact, in an article published this year, Kauer and Glenn have advocated that the problem be attacked with this in mind. In this clinic last year for the first time, Dr Mahoney did a one stage operation for carcinoma of the ampulla of Vater with excellent results. However, the attempt to accomplish the operation in one stage requires a patient in excellent condition, extreme surgical speed and skill, and the provision during the operation of large amounts of plasma and blood to combat the surgical shock which would otherwise develop during such a long procedure.

Following all this very interesting work on the surgical treatment of carcinoma of the ampulla of Vater, a tremendous advance was made in 1937 when Brunschwig operated on a

patient for carcinoma of the head of the pancreas in a two stage procedure and excised the entire head of the organ. Just previous to this, Lahey had recommended cholecystenterostomy rather than cholecystgastrostomy as a first stage, and Brunschwig made use of this in a rather unusual fashion (Fig 3).

In the same year George Crile, Jr reported another case of excision of the head of the pancreas for carcinoma, using a cholecystgastrostomy as the first stage, but, from the drawings presented, it would appear that the entire head was not excised (Fig 4). It has occurred to us that excision of the entire head for carcinoma of the lower end of the bile duct and ampulla is possibly as easy as the removal of a wedge-shaped section of pancreas, for this must involve the time-consuming ligation of innumerable small vessels, whereas, as will be shown, only two main arteries require ligation if the entire head of this organ is excised. This procedure will also conform more to the general principle of wide excision of tissue beyond the local area of tumor growth.

Fig 1 Illustration of the two stage procedure suggested by Whipple, Parsons and Mullins. Above, first operation. Left, second operation. (Courtesy Ann Surg 95: 25 or 763)

radical excision *en bloc* of the tumor by means of a two stage procedure remained unchanged. However he was disturbed by numerous instances in which recurring cholangitis and hepatitis followed the first stage in spite of the provision of a large stoma between the gall bladder and the stomach. It was apparent by this time that the lack of pancreatic secretion

did not interfere with the patient's nutrition. In fact, most of the patients constantly showed a gain in weight following the first stage of the operation. He proposed, therefore, a cholecystojejunostomy on the Roux principle, as shown in the accompanying diagram (Fig 2) and reported 3 cases, none of which had been followed by cholangitis.

One point which should be borne in mind is that the mesentery of that portion of the jejunum forming the anastomosis with the gall bladder should be sutured to the parietal peritoneum at a considerable distance from the duodenum in order that the division of the peritoneum along the lateral border of the duodenum, at the second operation can be accomplished without interfering with this leaf of mesentery. Furthermore, although Whipple recommends the ligation of the common duct just below the entrance of the cystic duct at the first operation. It is suggested that the common duct be left undisturbed so that one will not be hampered at the second operation by the presence of many adhesions in this region. If however the common duct has been opened for exploration during the first stage of the operation, it probably is wise to ligate it and leave a long silk suture for a marker as he suggests.

are used throughout. The pylorus is first divided and this immediately exposes the pancreas where a blunt instrument can be passed beneath the neck of the gland. Caution must be used to keep the instrument in close proximity to the deep surface of the gland for several important large vessels lie immediately behind it. The neck is then divided along the line shown in Fig 5b. We used the actual cautery for this division feeling that bleeding would thereby be better controlled and the danger of leakage of pancreatic secretion decreased. However, Tripodi and Sherwin, in recent experiments on excision of the pancreas in dogs, have shown that the stump of the pancreas heals equally well and shows no tendency toward leakage of its external secretion whether one uses the scalpel, actual cautery, or high frequency knife. It probably would be safer to make the division with the scalpel, since there is actually very little bleeding from this portion of the pancreas and one could then more easily identify and ligate the main pancreatic duct issuing from the body of the gland. The first part of the duodenum is then mobilized from above, no attempt being made to separate it from the pancreas, and in the course of this part of the dissection the gastroduodenal artery and common bile duct are ligated and divided.

Fig 8 Portion of the superior mesenteric vein has been removed to show the high origin and fan shaped distribution of the inferior pancreaticoduodenal artery

By dividing the pancreas at this point one immediately exposes the splenic and superior mesenteric veins where they join to form the portal vein, and it will be seen that the latter crosses the head of the pancreas in an oblique fashion, the superior mesenteric artery lying behind and hidden by the vein (Fig 6a). Numerous small veins issuing from the head of the pancreas enter the superior mesenteric vein on its pancreatic surface, and these must be ligated while the vein is gently retracted medially in order to expose the upper and medial margins of the head as shown in Figure 6b. From this point on in the operation we

the division of the pylorus. The dotted line indicates the line of incision through the neck of the pancreas.

OPERATIVE PROCEDURE

Last year I attempted an operation for excision of carcinoma of the head of the pancreas which presented several interesting problems. The first stage of this operation required a choledochojejunostomy due to the fact that the patient possessed a nonpatent cystic duct and a small, scarred gall bladder which could not be utilized in a short-circuiting operation.

Unfortunately this contributed to the patient's death following the second stage due to a separation of the suture lines as a result of traction on this region and consequent leakage of bile.

The second stage of the operation, as described by Brunschwig, is illustrated by Figures 5, 6 and 7. A transverse incision is employed to open the abdomen and silk sutures

Fig. 6. a, left. Exposure of the superior mesenteric vessels by division of the neck of the pancreas and the projection of the uncinate process behind and medial to these vessels. b, Retraction of the head of the pancreas laterally and the mesenteric vein medially the uncinate process

of the head thus being freed. Several pancreatic veins have been ligated, as have the gastroduodenal artery and the common bile duct. The so-called normal origin of the inferior pancreaticoduodenal artery is shown in this drawing.

Fig 7 The completed operation with gastroenterostomy not shown

are used throughout. The pylorus is first divided and this immediately exposes the pancreas where a blunt instrument can be passed beneath the neck of the gland. Caution must be used to keep the instrument in close proximity to the deep surface of the gland for several important large vessels lie immediately behind it. The neck is then divided along the line shown in Fig 5b. We used the actual cautery for this division feeling that bleeding could thereby be better controlled and the danger of leakage of pancreatic secretion decreased. However, Tripodi and Sherwin, in recent experiments on excision of the pancreas in dogs, have shown that the stump of the pancreas heals equally well and shows no tendency toward leakage of its external secretion whether one uses the scalpel, actual cautery, or high frequency knife. It probably would be safer to make the division with the scalpel, since there is actually very little bleeding from this portion of the pancreas and one could then more easily identify and ligate the main pancreatic duct issuing from the body of the gland. The first part of the duodenum is then mobilized from above, no attempt being made to separate it from the pancreas, and in the course of this part of the dissection the gastroduodenal artery and common bile duct are ligated and divided.

Fig 8 Portion of the superior mesenteric vein has been removed to show the high origin and fan shaped distribution of the inferior pancreaticoduodenal artery

By dividing the pancreas at this point one immediately exposes the splenic and superior mesenteric veins where they join to form the portal vein, and it will be seen that the latter crosses the head of the pancreas in an oblique fashion, the superior mesenteric artery lying behind and hidden by the vein (Fig 6a). Numerous small veins issuing from the head of the pancreas enter the superior mesenteric vein on its pancreatic surface, and these must be ligated while the vein is gently retracted medially in order to expose the upper and medial margins of the head as shown in Figure 6b. From this point on in the operation we

Fig 9 Depicting the usual origin, course, and distribution of the inferior pancreaticoduodenal artery described in most textbooks of surgery and anatomy

Fig. 6. a, left and b. T. side of the 24 dissections studied revealed high origin of the inferior pancreaticoduodenal artery as shown. (A section of the superior mesenteric vein as removed to clarify the picture)

Fig. 7. a, left and b. A high posterior origin of the inferior pancreaticoduodenal artery

encountered several interesting and unexpected difficulties. The duodenum has been mobilized by division of the lateral reflexion of peritoneum and by blunt dissection the hand can be placed behind the duodenum and head of the pancreas where these structures lie immediately adjacent to the vena cava and aorta. In order to carry the dissection around the medial border of the head it is necessary to provide some traction to free the uncinate process from its position beneath the superior mesenteric artery. When this maneuver was attempted in our patient he immediately developed a profound state of shock which persisted until the close of the operation and for 2 to 3 hours afterward in spite of all the usual methods which were used to combat it. We believe that this was due to the fact that the head of the pancreas is abundantly supplied

with sympathetic nerves issuing in a radiating fashion from the plexus around the root of the superior mesenteric artery. In a good many cases this traction can be avoided but it is suggested that in order to prevent this sympathetic reflex from operating, one should inject the region of the plexus with novocain as soon as the neck of the pancreas has been divided.

The next problem which we encountered was that the inferior pancreaticoduodenal artery does not always arise low on the superior mesenteric artery and proceed laterally in the interval between the pancreas and duodenum as described in most textbooks of surgery and anatomy. In the case under discussion it had its origin high up near the root of the artery and proceeded downward and outward, as shown in Figure 8. This caused us some concern inasmuch as we were doubtful whether or

Fig 12 Another case of high origin of the inferior pancreaticoduodenal artery and the only case in which its branches reached the pancreas and duodenum on its posterior aspect

not this vessel could be ligated at its origin without endangering the vitality of the third portion of the duodenum at that point where we intended to amputate it and turn in the distal end. We felt that primary ligation of this vessel and the gastroduodenal artery as early as possible in the operation would render the resection relatively bloodless and conserve much time otherwise occupied in the ligation of numerous small bleeding points. The operation should be completed by inverting the stump of remaining duodenum, closing the stump of the body of the pancreas with three or four silk mattress sutures and the provision of a posterior gastroenterostomy as shown in Figure 7. Our patient, however, was in such a severe stage of shock that we saved some time by sewing the stump of the duodenum to the distal end of the stomach. In the future it would be better to do the gastroenterostomy as the first step in the second stage rather than be faced with this at the close of the operation. Shock, if it develops at all, is most likely to occur when one uses traction on the head of the pancreas, and one should be in a position to close the abdomen at once. In our case this was accomplished with through-and-through wire sutures without drainage. The patient died 3 days later of bile peritonitis due to a leakage from the previous choledochojejunostomy and a complete thrombosis of the portal vein and its tributaries. I cannot ex-

Fig 13 The only case in the group in which no inferior pancreaticoduodenal artery was present.

plain the development of the portal thrombosis and it is regrettable that it occurred, for there was a concomitant gangrene of the stomach and jejunum so that we were unable to determine whether or not the ligation of the inferior pancreaticoduodenal artery interfered with the vitality of the duodenal stump.

STUDIES OF THE BLOOD SUPPLY OF THE HEAD OF THE PANCREAS AND DUODENUM

The finding of the high origin of the inferior pancreaticoduodenal artery led to an anatomical investigation of the blood supply of the head of the pancreas with particular reference to this artery. With the co-operation of Dr W B Hawkins in the department of pathology and Prof Karl Mason in the department of anatomy, 24 dissections were carried out, in each instance the operative approach described above being used, examples of these are illustrated by Figures 9 to 16. In only 8 of the subjects were we able to demonstrate the normal textbook picture of the artery as depicted in Figure 9. In 12 instances, comprising half of the subjects studied, the artery arose from a high position on the superior mesenteric, frequently from its posterior aspect (Figs 10a, b and 11a, b). The artery immediately breaks up into many smaller vessels which proceed in a fan-shaped distribution to the anterior surface of the pancreas and third portion of the duodenum. Figure 12 reveals a very high origin of the artery and is the only instance in which its branches reached the

Fig. 14. a, left, and b. The abnormal origin of the middle colic artery from the gastroduodenal artery

head on the posterior surface. This subject also presented a very high origin of the middle colic artery which then pursued a course across the duodenum at the point where it would be turned in during the operation. Further dissection of this group of high origins of the inferior pancreaticoduodenal artery revealed that, as a general rule the first intestinal branch arose from the posterior surface of the superior mesenteric artery above the duodenum and supplied the terminal portion. In these cases therefore, there probably exists an adequate blood supply to that portion of the duodenum which would be transected and turned in during the operation in spite of the high ligation

of the inferior pancreaticoduodenal artery at its point of origin.

One dissection revealed no vessel corresponding to the inferior pancreaticoduodenal (Fig. 13). The 3 subjects, illustrated by Figs. 14a, b and 15 show a most unusual and unsuspected anomaly. In 2 of these the middle colic artery has arisen as a main branch from the gastroduodenal. In such a case, it can be readily seen that ligation of the gastroduodenal artery early in the operation as suggested, before discovery of this anomaly might result in a serious impairment of the arterial supply of the transverse colon. With the exception of this anomaly the early ligation of the gastro-

Fig. 15. In this case the inferior pancreaticoduodenal artery arose from the middle colic artery

Fig. 16. Normal origin of inferior pancreaticoduodenal artery. Many anastomotic vessels supply the pancreas.

duodenal artery at its origin is possible in the operative technique described, for it was remarkably constant in its origin, course, and distribution in all 24 dissections. In the other case (Fig 15) the inferior pancreaticoduodenal artery is a branch from the middle colic, and here again an unfortunate arterial ligation would be possible. Figure 16 demonstrates a very peculiar arrangement of aberrant vessels forming a perplexing anastomosis on the anterior surface of the pancreas.

SUMMARY

1 A case is presented in which a two stage resection of the entire head of the pancreas for carcinoma was accomplished, and it is recommended that the first stage be that of a cholecystjejunostomy following the Roux principle as advocated by Whipple.

2 The actual excision of the entire head of the pancreas, rather than a partial wedge excision, together with the major portion of the duodenum, is feasible and can be greatly facilitated by ligating the gastroduodenal artery and the inferior pancreaticoduodenal artery early in the operation, thus the greater portion of the dissection is rendered relatively bloodless.

3 However, as a result of 24 dissections in which the various stages of the operation were carried out according to plan, certain marked deviations from the normal distribution of these vessels, as described in most textbooks of anatomy, have been exposed and might render this stage of the operation technically difficult.

4 These dissections disclosed that in half of the subjects studied the inferior pancreaticoduodenal arises high up on the superior mesenteric artery and is distributed in a fan-shaped manner downward and outward over the anterior surface of the gland.

5 The gastroduodenal artery is remarkably constant in its origin, course, and distribution,

but in 2 of the subjects studied it gave origin to the middle colic artery. It is, therefore, recommended that the origin and distribution of this vessel be determined before the gastroduodenal artery or the inferior pancreaticoduodenal artery are ligated.

6 In many cases traction laterally on the head of the pancreas is necessary in order to dislodge the uncinate process from its position beneath the superior mesenteric vessels. This maneuver may induce a reflex resulting in profound shock because of the large number of sympathetic nerves radiating to the pancreas from the mesenteric plexus. Therefore it is suggested that, as soon as the head of the pancreas is exposed, the plexus be infiltrated with novocain, in the hope that this complication, which we found extremely difficult to combat successfully, may be avoided.

7 The suggestion is made that the placing of a gastroenterostomy be the first step in the second stage of the operation.

AN ASEPTIC RESECTION OF THE STOMACH FOR CARCINOMA AND ULCER

EMILE HOLMAN M.D. F.A.C.S., San Francisco, California

CARCINOMA of the stomach is frequently accompanied in patients of advanced age by anemia, debility, poor nutrition and impaired resistance to infection. Every effort is made before operation upon such patients to minimize the hazards imposed by these conditions by transfusions, by a high protein, high carbohydrate diet, and by the administration of vitamin concentrates for 7 to 10 days preceding the operation. Occasionally sulfanilamide and, more recently, sulfathiazole have been administered for 24 hours before the operation and for 48 hours after the operation. Despite these various precautions, which may not all be realized because of pyloric obstruction the hazards remain great. In one clinic, a mortality of 50 per cent has been recorded following resections. In the past 10 years at the Stanford clinic, the mortality in the resected cases has been 10 per cent. In an effort to reduce this mortality still further an aseptic resection of the stomach has been developed in the past 18 months, independently of a similar development in Wangenstein's clinic (6). Although primarily intended for applica-

tion in resection for carcinoma, in which, due to achlorhydria, infection is more imminent, we are now employing it also in resection for ulcer. In resection for ulcer it is freely conceded that in the majority of cases the contamination encountered by entering the lumen of the stomach, the duodenum, or the jejunum does not usually impose a serious risk of infection. However, since one or two patients in every hundred cases of resection of the stomach suffer infected wounds, and occasionally peritonitis and death, an aseptic technique should diminish or prevent such catastrophes. By such improvements and by constant vigilance and endeavor does the surgeon reduce "the irreducible minimum."

The accompanying illustrations show the various steps in technique.

In all upper abdominal surgery, the optimum position of the patient on the table is obtained by elevation of the upper half of the body, permitting the stomach and liver to descend below the costal margin, and the small intestines to fall into the pelvis out of the operative wound (Fig. 1a). This prevents exposure and handling of the small bowel, both important factors in postoperative distention. In this position also pulmonary

Fig. 1a.

Fig. 1b.

From the Stanford University Medical School.
Presented before the Pacific Coast Surgical Association February 20, 1941.

Fig 2a

Fig 2b

ventilation and respiratory exchange is improved through a more efficiently working diaphragm. A kidney elevator maintains the normal lordosis and elevates the intra-abdominal contents into the wound. By flexion at the hips, the lower half of the body is elevated above cardiac level to prevent pooling of blood in the lower extremities incident to the general vasodilatation that accompanies a general anesthetic.

A midline incision (Fig 1b) provides easy accessibility both to duodenum and to the cardia of the stomach. On occasion the left costal cartilages close to the sternum are divided without entering the chest, and the ligamentous attachment of the left lobe of the liver is divided to expose the esophageal gastric junction. The incision may be prolonged on either side of the umbilicus as circumstances dictate.

In mobilizing the omentum or the gastrohepatic mesentery, the tissues containing the blood vessels are not crushed by the application of clamps (Fig 2a). Instead, the tissues are separated by blunt dissection in an avascular area, two ligatures are applied and tied, and the tissue cut between them. Where the tissue cannot be separated easily as in the gastrohepatic mesentery, the two ligatures are applied by transfixion needles introduced through an avascular area, and the vessel is divided be-

tween them. The purpose of avoiding clamps is to minimize the crushing and devitalization of tissues in the operative area—thus (1) reducing the postoperative febrile reaction, (2) eliminating as far as possible the need of the body to absorb dead tissue, and (3) minimizing still further the hazard of infection through possible bacterial contamination of avascular tissue capable of acting as an excellent culture medium. It is believed that if the cells in the avascular tissue beyond the ligature are not crushed, their nutrition may be maintained by becoming adherent to surrounding structures or by imbibition of nutrition from peritoneal fluid until revascularization is effected.

The stomach is mobilized, the lesser curvature almost completely, the greater curvature well up to and sometimes including the gastrosplenic ligament (Fig 2b). Two Payr clamps are applied distal to the pylorus and the duodenum is transected between them with a cautery. The distal duodenal stump is seared by applying the cautery along the Payr clamp for approximately 15 seconds to insure coagulation of the vessels in the divided duodenal wall. A continuous Parker-Kerr basting stitch of No. 0 chromic catgut on an atraumatic needle is applied to the duodenum with the Payr clamp still in place (Fig 2b, a), thus insuring the turning in of the raw edges on

Fig. 5a.

Fig. 5b.

removal of the clamp. This first line of closure is in turn buried by reversing the direction of the same catgut suture back to its site of origin (Fig. 5b). A third line of interrupted black silk sutures is applied (Fig. 5b c) thus burying the two previously placed continuous catgut closures.

In line with previous observations (5) continuous nonabsorbable sutures are never used in gastrointestinal anastomoses. Reichert and Holman found in cleared specimens of intestinal anastomoses of 3 to 6 weeks duration that the interrupted nonabsorbable silk sutures had migrated so that they lay either underneath the peritoneum, or had been discharged into the lumen and lost. The determining factor seemed to be whether or not the suture had passed into the infected mucosa. If the needle was made purposely to penetrate the lumen, the stitch was discharged into the lumen. If the needle was applied to pass through the submucosa without entering the lumen, the stitch would eventually lie free on the serosal surface covered only by peritoneum. Therefore a continuous nonabsorbable

Fig. 5c.

Fig. 5d.

stitch might lie partly underneath the peritoneum, and partly inside the lumen, thus providing a continuous "seal" from sterile peritoneum to the infected lumen. Hence, the necessity of avoiding the use of continuous nonabsorbable sutures in intestinal anastomoses.

The Parker Kerr *inversion* stitch is a fundamental procedure in surgery. It turns into the intestinal lumen the raw contaminated edge of the divided bowel wall and approximates serosa to serosa (Fig. 3b). As early as 1813 Bichat enunciated this elemental fact, to be applied by Lembert in 1826 to intestinal suturing. Despite the insistence of these early authors that mucosa to-mucosa will not heal, that serosa to-serosa is a *sine qua non* in inter-

Fig. 4a.

Fig. 4b.

Fig 6a

Fig 6b

tinal suture, some surgeons are still fond of using either the mattress *eversion* stitch for approximation of surfaces and control of bleeding, or the de Petz clamp, which everts the unsterile bowel edges and applies constricting metal staples to control bleeding (Fig 3a). The raw edges approximated by this mucosa-to-mucosa stitch are then buried by a serosa-to-serosa suture, thus fulfilling the law of intestinal suturing. However, the buried raw edges of the bowel, infected and avascular, theoretically may invite the formation of small abscesses which may burst into the lumen or the peritoneal cavity, and may cause failure in the line of suture with the formation either of an external fistula or a peritonitis. Granting that this may occur only rarely, its very possibility should be eliminated by avoiding the *eversion* stitch in intestinal suturing.

Payr or narrow crushing clamps are applied to the stomach in one of two ways (Fig 4a and b), as illustrated, depending upon the ease of application. The stomach is divided with a cautery, and the cut edges of the stomach wall are seared by passing the hot cautery back and forth over the surface of the clamp for 15 seconds. Recently, following the observations of Gerbode in the Stanford Surgical Laboratory, instead of the stomach being divided flush with the crushing clamp, a small cuff of the wall is left projecting 1 to 2 millimeters beyond the clamp. This cuff is seared, thus coagulating and closing the open ends of blood

vessels without damaging the gastric wall on the proximal side of the clamp, which may occur if the clamp is excessively heated. Gerbode's observations indicate that the portion of the bowel wall devitalized by the crushing clamp and by the cauterization separates and drops off into the lumen within 48 hours. The resulting raw surface between the opposed intestinal walls which is usually very narrow is covered with mucosa within 18 to 21 days.

The remnant of stomach is partially closed along the lesser curvature, first by a continuous Parker-Kerr basting stitch of chromic catgut on an atraumatic needle (Fig 5a), thus inverting the raw seared surfaces of the divided stomach wall. The continuous suture is in turn buried by interrupted silk sutures (Fig 5b). A Payr or narrow-bladed Martzloff or Wangenstein clamp is applied tangentially on the jejunal wall as illustrated in Figure 6a and a segment is removed by cautery, the edges of the bowel being seared again for about 15 seconds to control bleeding. Careful inspection of the removed segment should reveal a mucosal surface along its entire extent.

The loop of jejunum is applied to the stomach remnant (Fig 6b), proximal arm to right of opening, distal arm to greater curvature.

The two Payr or Wangenstein narrow-bladed clamps on the remnant of stomach and on the jejunum are approximated anterior to the colon (Fig 7). The anastomosis is effected by one of two ways. A row of interrupted

Fig. 7a

Fig. 7b.

mattress sutures of silk is applied posteriorly the needle and suture paralleling the clamps as close as subsequent tying will permit. After all have been applied, they are tied.

A row of interrupted mattress silk sutures are applied anteriorly the needle and suture again paralleling the clamps (Fig. 7b). The clamps are removed and the stitches tied separately. A few additional sutures are applied at the two extremities of the stoma to insure a leak-proof closure. After the last stitch has been tied the new gastrojejunal stoma is opened by gentle digital manipulation.

This method of approximation of serosal surfaces for re-establishing intestinal continuity (Fig. 7) as used in our early aseptic resections, has been superseded in later resec-

tions by utilizing Martzloff's modification of the Parker Kerr basting stitch as suggested by Wangenstein. The clamps are rotated away from the proposed posterior line of closure. A continuous basting stitch of No. 0 chromic catgut on an atraumatic needle is applied alternately to the contiguous gastric and jejunal serosal surfaces lying posterior to the clamps (Fig. 8a).

The clamps are rotated toward the posterior suture and a second continuous Parker Kerr basting stitch of No. 0 chromic catgut is applied alternately to the contiguous gastric and jejunal surfaces lying anterior to the clamps (Fig. 8b). The clamps are removed, the two sutures pulled taut, thus accurately approximating the serosal surfaces posteriorly and

Fig. 8a.

Fig. 8b.

Fig. 8c.

Fig 9b

Fig 9c.

anteriorly The two sutures are tied together at each end (Fig 8c, a, b) This line of continuous catgut suture is in turn buried by interrupted silk sutures applied posteriorly and anteriorly Digital manipulation insures the opening of the stoma

In resections for ulcer in which a larger remnant of stomach remains than in resection for carcinoma, this completes the operation

The larger remnant of stomach following resection for ulcer does not recede into the left upper quadrant, and therefore obstructing angulation of either of the two jejunal arms of the gastrojejunal anastomosis is not so imminent The *anterior* gastrojejunostomy also contributes to diminishing the danger of such obstructing angulation Moreover, in resections for ulcer, a jejunojejunostomy between these two jejunal arms of the gastrojejunostomy is strictly avoided, as it is considered highly undesirable to deflect the alkaline duodenal and pancreatic secretions through an enteroenterostomy, away from the gastroenterostomy The neutralization, preferably in the stomach, of the acid gastric secretions by the alkaline duodenal secretions is most effective in preventing jejunal ulceration

In all cases of subtotal resections for cancer, in contrast to resection for ulcer, the anterior gastrojejunostomy with a complementary jejunojejunostomy is considered practically obligatory (Figs 9 and 10) It is our aim in resections for cancer to remove the entire

lesser curvature together with the gland bearing tissues in the gastrohepatic mesentery and most of the greater curvature The small remnant of stomach resulting from this procedure recedes high into the left upper quadrant, under the left diaphragm Were a posterior gastrojejunostomy performed through a rent in the mesocolon, a drag on the mesocolon would occur, and obstructing angulation of one or both arms of the jejunum would be imminent Even if this immediate danger were averted, the hazard of a jejunal ulcer or of a gastrojejunocolic fistula is greatly increased by tension on the anastomosis from a fixed or short mesocolon I propose as an axiom in gastric surgery that following any gastric anastomosis, the stomach must be *comfortable*, both at rest and in activity Any interference with the effective motility of the stomach, either by the fixed or short mesocolon or by the stomach being joined to the fixed portion of the jejunum, will surely lead to tragic consequences In resections for cancer, therefore, an anterior gastrojejunostomy is invariably performed and since there is no danger of jejunal ulceration incident to the deflection of the alkaline duodenal secretions away from the gastrojejunal anastomosis, an enteroenterostomy is also performed between the two arms of the jejunum leading to and from the gastric stoma Two thin-bladed Martszloff or Wangenstein crushing clamps are applied tangentially on the jejunal wall (Fig 9a), a segment

Fig. 7a.

Fig. 7b.

mattress sutures of silk is applied posteriorly, the needle and suture paralleling the clamps as close as subsequent tying will permit. After all have been applied, they are tied.

A row of interrupted mattress silk sutures are applied anteriorly the needle and suture again paralleling the clamps (Fig. 7b). The clamps are removed and the stitches tied separately. A few additional sutures are applied at the two extremities of the stoma to insure a leak-proof closure. After the last stitch has been tied, the new gastrojejunal stoma is opened by gentle digital manipulation.

This method of approximation of serosal surfaces for re-establishing intestinal continuity (Fig. 7) as used in our early aseptic resections, has been superseded in later resec-

tions by utilizing Martzloff's modification of the Parker Kerr basting stitch as suggested by Wangersteen. The clamps are rotated away from the proposed posterior line of closure. A continuous basting stitch of No. 0 chromic catgut on an atraumatic needle is applied alternately to the contiguous gastric and jejunal serosal surfaces lying posterior to the clamps (Fig. 8a).

The clamps are rotated toward the posterior suture and a second continuous Parker Kerr basting stitch of No. 0 chromic catgut is applied alternately to the contiguous gastric and jejunal surfaces lying anterior to the clamps (Fig. 8b). The clamps are removed, the two sutures pulled taut, thus accurately approximating the serosal surfaces posteriorly and

HUMAN BITES OF THE HAND

HARRY MILLER, M D , and JAMES M WINFIELD, M D , F A C S ,
Detroit, Michigan

EXPERIENCE in many communities has yielded abundant proof of the danger which attends neglect of wounds contaminated with human mouth organisms. As the concomitant sequelae and resultant functional disturbances are often of a most serious nature, the importance of the correct management of the early and late human bite lesions cannot be over-emphasized. There is a definite tendency for these infections, when once established, to extend and to invade into deeper and more vital structures, the lesions rapidly becoming foul smelling, necrotizing, and resistant.

The organisms implanted in the tissues of the hand are often most virulent. The part played by such anaerobes as the fusiform bacillus and the spirochete of Vincent has been repeatedly pointed out. Although these organisms are not always demonstrable in cultures and smears from human bite wounds, dark field examination of fresh wet smears will demonstrate their presence in a higher percentage of instances. Anaerobic cultures observed over a period of 7 to 10 days will often yield much information. Streptococci and staphylococci alone and in symbiosis, as well as other contaminants such as the colon bacillus, various fungi and occasionally the *Spirocheta pallida* play an important rôle in producing and prolonging these necrotizing infections.

In order to gain a lucid concept of the problems involved in the prophylaxis and treatment of these lesions one must appreciate the anatomic complexity of the tissues which predisposes to extension of infection rather than to localization, particularly under conditions of neglect, as well as the low resistance of fibrous connective tissue and cartilage, to infection.

A knowledge of the mechanism of production, the usual sites of injury, the extent and

depth of the lesion, and the possible course of extension of the infection is of considerable aid in the intelligent management of these cases.

Human bite injuries usually occur during the course of fist fights or drunken biting brawls. Consequently, the lesions range from actual bites of the phalanges and hand to puncture wounds and lacerations produced by a fist striking exposed teeth. When the closed fist is used in striking a blow the knuckles of the second and third metacarpals receive the major force of the impact. This is primarily due to the fact that these bones are longer and stronger than the other metacarpals and, furthermore, they are more immobile. In this position the dorsal ligaments, extensor tendons, and skin are tightly stretched across the joint, and a blow on the projecting head of the metacarpal will easily cause a sharp, resisting surface to penetrate the joint cavity or to damage underlying structures (Fig 1).

A more rare mechanism, that of the sucking of hangnails or of clean lacerated wounds by the patient or a concerned bystander, will account for contamination with mouth organisms in a small number of cases. One of the patients included in our group of late infected cases acquired a severe infection following the biting of a hangnail.

In reviewing our early human bite wounds we have encountered almost twice as many lacerations of the fingers as of the knuckles. In the late cases the converse is true. The wounds of the phalanges occur predominantly on the dorsum, the palmar surface only occasionally being involved.

In regard to the extent and depth of the lesions, the injury may present itself as (1) a simple abrasion over the phalanges, knuckles, or palmar surface of the hand or wrist, involving only the epidermis (Fig 2), (2) a complete avulsion of segments of skin, subcutaneous structures and occasionally of bone (Fig 3), (3) a penetrating laceration either partially or completely severing the extensor tendon (Fig

Fig. 10e.

of bowel wall is removed by the cautery the edges are seared for control of bleeding and an anastomosis is effected by one of two methods (1) by interrupted mattress silk sutures applied posteriorly and anteriorly parallel to the clamps (Fig. 9b and c) or (2) by the Martindale application of the Parker Kerr basting stitch (Fig. 10d and e). The latter procedure is now considered preferable. A continuous No. 0 chromic catgut suture is applied paralleling the clamps posteriorly, the suture passing alternately from one jejunal wall to the contiguous surface of the other (Fig. 10a). The posterior suture remains loose while the clamps are rotated and a similar continuous suture of No. 0 chromic catgut is applied, paralleling the clamps anteriorly (Fig. 10b). The two clamps are removed, and both sutures are pulled taut, thus approximating the apposed serosal surfaces and inverting the raw edges of the jejunum into the lumen (Fig. 10c, a-b). These two catgut sutures are tied at both ends without puckering and without reducing the size of the anastomotic opening. The entire anastomosis is reinforced

with interrupted silk sutures (Fig. 10d). Digital manipulation insures opening of the stoma (Fig. 10e).

Any available omentum is brought up to lie between the under surface of the incision in the abdominal wall and the underlying viscera. The wound is closed in layers.

In numerous experimental anastomoses and in 31 clinical resections of the stomach for cancer and ulcer no hemorrhage has occurred or deaths, either from leakage or peritonitis. In not a single patient have we had an infection of the wound or evidence of a localized peritonitis.

HUMAN BITES OF THE HAND

HARRY MILLER, M D , and JAMES M WINFIELD, M D , F A C S ,
Detroit, Michigan

EXPERIENCE in many communities has yielded abundant proof of the danger which attends neglect of wounds contaminated with human mouth organisms. As the concomitant sequelae and resultant functional disturbances are often of a most serious nature, the importance of the correct management of the early and late human bite lesions cannot be over-emphasized. There is a definite tendency for these infections, when once established, to extend and to invade into deeper and more vital structures, the lesions rapidly becoming foul smelling, necrotizing, and resistant.

The organisms implanted in the tissues of the hand are often most virulent. The part played by such anaerobes as the fusiform bacillus and the spirochete of Vincent has been repeatedly pointed out. Although these organisms are not always demonstrable in cultures and smears from human bite wounds, dark field examination of fresh wet smears will demonstrate their presence in a higher percentage of instances. Anaerobic cultures observed over a period of 7 to 10 days will often yield much information. Streptococci and staphylococci alone and in symbiosis, as well as other contaminants such as the colon bacillus, various fungi, and occasionally the *Spirocheta pallida* play an important rôle in producing and prolonging these necrotizing infections.

In order to gain a lucid concept of the problems involved in the prophylaxis and treatment of these lesions one must appreciate the anatomic complexity of the tissues which predisposes to extension of infection rather than to localization, particularly under conditions of neglect, as well as the low resistance of fibrous connective tissue and cartilage, to infection.

A knowledge of the mechanism of production, the usual sites of injury, the extent and

depth of the lesion, and the possible course of extension of the infection is of considerable aid in the intelligent management of these cases.

Human bite injuries usually occur during the course of fist fights or drunken biting brawls. Consequently, the lesions range from actual bites of the phalanges and hand to puncture wounds and lacerations produced by a fist striking exposed teeth. When the closed fist is used in striking a blow the knuckles of the second and third metacarpals receive the major force of the impact. This is primarily due to the fact that these bones are longer and stronger than the other metacarpals and, furthermore, they are more immobile. In this position the dorsal ligaments, extensor tendons, and skin are tightly stretched across the joint, and a blow on the projecting head of the metacarpal will easily cause a sharp, resisting surface to penetrate the joint cavity or to damage underlying structures (Fig 1).

A more rare mechanism, that of the sucking of hangnails or of clean lacerated wounds by the patient or a concerned bystander, will account for contamination with mouth organisms in a small number of cases. One of the patients included in our group of late infected cases acquired a severe infection following the biting of a hangnail.

In reviewing our early human bite wounds we have encountered almost twice as many lacerations of the fingers as of the knuckles. In the late cases the converse is true. The wounds of the phalanges occur predominantly on the dorsum, the palmar surface only occasionally being involved.

In regard to the extent and depth of the lesions, the injury may present itself as (1) a simple abrasion over the phalanges, knuckles, or palmar surface of the hand or wrist, involving only the epidermis (Fig 2), (2) a complete avulsion of segments of skin, subcutaneous structures and occasionally of bone (Fig 3), (3) a penetrating laceration either partially or completely severing the extensor tendon (Fig

of bowel wall is removed by the cautery the edges are scared for control of bleeding and an anastomosis is effected by one of two methods (1) by interrupted mattress silk sutures applied posteriorly and anteriorly parallel to the clamps (Fig 99b and c) or (2) by the Martzloff application of the Parker Kerr basting stitch (Fig 100d and e) The latter procedure is now considered preferable. A continuous No. 0 chromic catgut suture is applied paralleling the clamps posteriorly the suture passing alternately from one jejunal wall to the contiguous surface of the other (Fig 100a) The posterior suture remains loose while the clamps are rotated and a similar continuous suture of No. 0 chromic catgut is applied, paralleling the clamps anteriorly (Fig 100b) The two clamps are removed, and both sutures are pulled taut, thus approximating the apposed serosal surfaces and inverting the raw edges of the jejunum into the lumen (Fig 100c, a-b) These two catgut sutures are tied at both ends without puckering and without reducing the size of the anastomotic opening The entire anastomosis is reinforced

with interrupted silk sutures (Fig 100d) Digital manipulation insures opening of the stoma (Fig 100e)

Any available omentum is brought up to lie between the under surface of the incision in the abdominal wall and the underlying viscera. The wound is closed in layers.

In numerous experimental anastomoses and in 31 clinical resections of the stomach for cancer and ulcer no hemorrhage has occurred or deaths either from leakage or peritonitis. In not a single patient have we had an infection of the wound or evidence of a localized peritonitis.

HUMAN BITES OF THE HAND

HARRY MILLER, M D , and JAMES M WINFIELD, M D , F A C S ,
Detroit, Michigan

EXPERIENCE in many communities has yielded abundant proof of the danger which attends neglect of wounds contaminated with human mouth organisms. As the concomitant sequelae and resultant functional disturbances are often of a most serious nature, the importance of the correct management of the early and late human bite lesions cannot be overemphasized. There is a definite tendency for these infections, when once established, to extend and to invade into deeper and more vital structures, the lesions rapidly becoming foul smelling, necrotizing, and resistant.

The organisms implanted in the tissues of the hand are often most virulent. The part played by such anaerobes as the fusiform bacillus and the spirochete of Vincent has been repeatedly pointed out. Although these organisms are not always demonstrable in cultures and smears from human bite wounds, dark field examination of fresh wet smears will demonstrate their presence in a higher percentage of instances. Anaerobic cultures observed over a period of 7 to 10 days will often yield much information. Streptococci and staphylococci alone and in symbiosis, as well as other contaminants such as the colon bacillus, various fungi, and occasionally the *Spirocheta pallida* play an important rôle in producing and prolonging these necrotizing infections.

In order to gain a lucid concept of the problems involved in the prophylaxis and treatment of these lesions one must appreciate the anatomic complexity of the tissues which predisposes to extension of infection rather than to localization, particularly under conditions of neglect, as well as the low resistance of fibrous connective tissue and cartilage, to infection.

A knowledge of the mechanism of production, the usual sites of injury, the extent and

depth of the lesion, and the possible course of extension of the infection is of considerable aid in the intelligent management of these cases.

Human bite injuries usually occur during the course of fist fights or drunken biting brawls. Consequently, the lesions range from actual bites of the phalanges and hand to puncture wounds and lacerations produced by a fist striking exposed teeth. When the closed fist is used in striking a blow the knuckles of the second and third metacarpals receive the major force of the impact. This is primarily due to the fact that these bones are longer and stronger than the other metacarpals and, furthermore, they are more immobile. In this position the dorsal ligaments, extensor tendons, and skin are tightly stretched across the joint, and a blow on the projecting head of the metacarpal will easily cause a sharp, resisting surface to penetrate the joint cavity or to damage underlying structures (Fig 1).

A more rare mechanism, that of the sucking of hangnails or of clean lacerated wounds by the patient or a concerned bystander, will account for contamination with mouth organisms in a small number of cases. One of the patients included in our group of late infected cases acquired a severe infection following the biting of a hangnail.

In reviewing our early human bite wounds we have encountered almost twice as many lacerations of the fingers as of the knuckles. In the late cases the converse is true. The wounds of the phalanges occur predominantly on the dorsum, the palmar surface only occasionally being involved.

In regard to the extent and depth of the lesions, the injury may present itself as (1) a simple abrasion over the phalanges, knuckles, or palmar surface of the hand or wrist, involving only the epidermis (Fig 2), (2) a complete avulsion of segments of skin, subcutaneous structures and occasionally of bone (Fig 3), (3) a penetrating laceration either partially or completely severing the extensor tendon (Fig

Fig. Region of knuckle. Mechanism of injury and implantation of infection.

4) (4) a wound which may have opened into the dorsal subcutaneous space subtendinous bursa dorsal subaponeurotic space or the joint cavity (Fig 5)

In 1930 Mason and Koch published a paper on human bite infections of the hand in which they demonstrated experimentally the lines of spread of infectious agents from the region of the metacarpophalangeal joint. This paper has been unsurpassed in the presentation of essentials and remains the outstanding contribution on this subject.

Obviously abrasions and avulsion lacerations offer little opportunity for the establishment of an anaerobic infection. Lacerations, however which have penetrated the subcutaneous layers and opened into the subcutaneous tissues and joints, present ideal conditions for the production of fetid necrotizing infections because of the relatively anaerobic conditions, the low resistance of fibrous tissue and synovial membranes the anatomic complexity of structures favoring the spread of infection and the presence of traumatized

Fig 2.

Fig 3.

Fig 4.

tissue. Consequently, the infections occurring on the dorsal aspect of the hand in and about the metacarpophalangeal joint potentially and actually carry the graver prognosis. Because of the shift of tissues particularly about the knuckles, infection may be carried from an original point of entrance to a relatively distant area (Fig 1).

Infection occurring from an injury over the proximal phalanx may extend both superficial and deep to the expansion of the extensor tendon (Fig 6a). From this position it may extend along the lumbrical and interosseous tendons to involve the lumbrical space.

Laceration of the extensor tendon with the implantation of infection but without penetration into the joint may occur. Here the extension of infection will be extracapsular and subtendinous, the subtendinous bursa and subaponeurotic space becoming contaminated (Fig 6a). Should the joint be infected, infection may penetrate into the subtendinous bursa and subaponeurotic space as well as under the expansion of the extensor tendon over the proximal phalanx (Fig 6b) from which point infection will travel, as described, namely, to the lumbrical canal and large fascial spaces in the palm of the hand (Fig 7).

The dorsal subcutaneous space is usually involved early. This follows subcutaneous penetration with or without laceration or displacement of the tendon or extension into the joint.

The flexor tendons and their synovial sheaths are rarely invaded from behind. A dense fibrous sheath and the accessory volar ligament serve as an adequate barrier. Late in the course of infection, especially in neglected cases, the flexor tendon sheaths may be invaded.

Believing the results obtained by those surgeons using chemical and electrocautery

Fig 5 Penetration of the joint cavity

methods in the primary treatment of early human contaminated wounds are not entirely satisfactory (1, 2, 3, 5, 8), we have followed in our clinic the suggestion made by Mason and Koch in 1930 of cleansing the wound with soap and water combined with gentle débridement. The recognition of early human bites as such is often quite difficult. Falsification of history is common especially in the white patient, and often results in contraindicated primary suture. A definite and comprehensive regimen has been developed, comprising a searching history, complete examination, and treatment.

The routine treatment employed is as follows. The area about the wound is gently washed with soap and water for 5 minutes following which the wound itself is thoroughly washed with soap and water and irrigated with saline for a further period of 10 minutes. Following this procedure, the edges are gently retracted and the lesion examined, in order to determine the extent of injury if possible. These wounds are not probed since the information obtained is meager and the danger of carrying infectious agents more deeply into the tissues is great. Following mechanical cleansing and a very limited débridement, wet dressings are applied. No attempts are made to repair the rent in the joint capsule. Hands are splinted in the position of function. Lacerations are never sutured nor are injuries to

deeper structures repaired. The major catastrophes in our series have occurred in those cases in which wounds were primarily sutured. Patients return daily for examination and if there is joint involvement, are usually hospitalized. In certain of the initial cases in this series patients were observed and treated in conjunction with Dr. R. E. Speers who has reported these previously. A total number of 61 early human bites of the hand have been given prophylactic treatment during the past 3 years. All patients seen within 4 hours after the occurrence of injury were considered early cases. Friedrich has pointed out that a lag phase of 6 hours exists before organisms contaminating a wound become acclimated to the human tissues. This lag phase in the case of organisms transferred from the human mouth is greatly shortened and there may be only a brief interval before the organisms are accustomed to their new environment. Those cases already presenting swelling and evidence of infectious extension were not included in this series of early cases even if patients were seen within the 4 hour period and were considered as late cases.

The accompanying table illustrates an interesting grouping of these injuries (Table I). It will be noted that 34 lesions involved the fingers while 18 occurred in the region of the knuckle. Of the total number of cases, 5 showed mild inflammatory reaction characterized by swelling and tenderness without suppuration and only 1 gave evidence of gross infection. Two of the knuckle injuries exhibit inflammation had been sutured primarily due to falsification of history but the sutures were removed almost immediately and the wound treated as a human bite. One of the compound fractures with the tip of the ter-

*One additional case with extensive, multiple injuries of the 5th finger and dorsum of the hand became grossly infected.

mild inflammation (Fig. 3). The compound fractures were usually hospitalized for a short period. The case referred to in the footnote was a most extensive injury, the fifth finger having been almost completely bitten off at the base of the proximal phalanx, tooth injuries of the third and fourth metacarpophalangeal joints and 3 lacerations over the dorsum of the hand. It was necessary to remove the fifth finger. The third and fourth metacarpophalangeal joints became stiff and the dorsal skin sloughed requiring a subsequent graft. Obviously gross suppuration occurred in this hand but we were able to save the major portion of the hand and to obtain a fair functional result. In none of the early cases except the last mentioned was it necessary to resort to amputation.

A more complete analysis has been made of the last 27 cases. In this group 10 were knuckle injuries, 5 of these occurring on the third right knuckle and 1 on the third left knuckle. Two occurred on the second right knuckle. Of the 17 finger injuries the first, second and fifth right fingers were most commonly involved. There were 10 extensor tendon lacerations and 1 flexor tendon laceration. The metacarpophalangeal joint was known to be entered in 3 instances, but no doubt lacerations involving the joint were more frequent than this, as the positive determination of the extent of the injury in this region is often difficult to ascertain.

Over 60 per cent of the cases were between the ages of 15 and 25 years, 8 being males,

Fig 8 Usual type of incision for adequate joint drainage

9 females, 19 were colored, and 8 white. Of 22 cases the functional result in 20 was excellent, good in 1, and poor in 1 (cases described previously).

The average wound healing time for the whole series of 61 cases was 8.5 days and for the group of 27 cases 9.9 days.

The after-care consisted essentially of splinting and the application of continuous saline, boric acid, or magnesium sulphate soaks for a period of 48 hours. The wet dressings were discontinued at this time if the wounds remained clean. Splinting was continued to complete healing.

This relatively simple course of management of early human bite injuries has given results which have been most gratifying. Unfortunately, the patient, when first seen often has a fully established infection, and regardless of the adequacy of treatment, frequently is condemned to a prolonged illness which may result in loss of parts and occasionally in loss of life.

Fig 9 Healed incision. Drainage subcutaneous, subaponeurotic, and joint spaces

In marked contrast to the prophylactic treatment and management of the early human bite injuries, is the therapeutic problem presented by the late infected human bites. These wounds are already in serious conditions, and sometimes extensively infected. As in other infections of this type, adequate surgery is essential with emphasis on somewhat earlier and more radical drainage. In general, the basic principles enunciated by Kanavel, Koch, Mason, and others relative to the treatment of established hand infections should be adhered to scrupulously. It should be unnecessary and is obviously impractical to outline the treatment in the most minute detail. Suffice it to say, that under general anesthesia, and in a bloodless field, the hand is thoroughly cleansed with soap and water. Then an extremely careful, meticulous débridement is performed, with removal of as much infected, gangrenous sloughing tissue as possible, and in addition with adequate drainage for all areas of infection. Definite mention should be made regarding metacarpophalangeal joint infections. The joint capsule should be opened transversely by a 1 to a 1.5 centimeter incision which usually gives sufficient drainage (Fig 8). As has been pointed out earlier in the

Fig. 7. Lambribral space and palmar extension.

deeper structures repaired. The major catastrophes in our series have occurred in those cases in which wounds were primarily sutured. Patients return daily for examination and if there is joint involvement are usually hospitalized. In certain of the initial cases in this series patients were observed and treated in conjunction with Dr. R. E. Speira who has reported these previously. A total number of 61 early human bites of the hand have been given prophylactic treatment during the past 3 years. All patients seen within 4 hours after the occurrence of injury were considered early cases. Friedrich has pointed out that a lag phase of 6 hours exists before organisms contaminating a wound become acclimated to the human tissues. This lag phase in the case of organisms transferred from the human mouth is greatly shortened and there may be only a brief interval before the organisms are accustomed to their new environment. Those cases already presenting swelling and evidence of infectious extension were not included in this series of early cases even if patients were seen within the 4 hour period and were considered as late cases.

The accompanying table illustrates an interesting grouping of these injuries (Table I). It will be noted that 34 lesions involved the fingers while 18 occurred in the region of the knuckle. Of the total number of cases, 5 showed mild inflammatory reaction characterized by swelling and tenderness without supuration and only 1 gave evidence of gross infection. Two of the knuckle injuries exhibiting inflammation had been sutured primarily due to falsification of history, but the sutures were removed almost immediately and the wound treated as a human bite. One of the compound fractures with the tip of the terminal phalanx completely bitten off showed

*One additional case with extensive amputation in part of the fifth finger and dorsum of the hand became grossly infected.

mild inflammation (Fig. 3). The compound fractures were usually hospitalized for a short period. The case referred to in the footnote was a most extensive injury, the fifth finger having been almost completely bitten off at the base of the proximal phalanx, tooth injuries of the third and fourth metacarpophalangeal joints and 3 lacerations over the dorsum of the hand. It was necessary to remove the fifth finger. The third and fourth metacarpophalangeal joints became stiff and the dorsal skin sloughed requiring a subsequent graft. Obviously gross supuration occurred in this hand but we were able to save the major portion of the hand and to obtain a fair functional result. In none of the early cases, except the last mentioned, was it necessary to resort to amputation.

A more complete analysis has been made of the last 27 cases. In this group 10 were knuckle injuries, 5 of these occurring on the third right knuckle and 1 on the third left knuckle. Two occurred on the second right knuckle. Of the 17 finger injuries, the first second and fifth right fingers were most commonly involved. There were 10 extensor tendon lacerations and 1 flexor tendon laceration. The metacarpophalangeal joint was known to be entered in 3 instances, but no doubt lacerations involving the joint were more frequent than this, as the positive determination of the extent of the injury in this region is often difficult to ascertain.

Over 60 per cent of the cases were between the ages of 5 and 25 years, 18 being males,

Fig 12 Incision for drainage of lumbrical space

sulphate solutions, we have utilized and rather favor the use of Dakin's solution, it being our impression that the wounds remained cleaner and that sloughs separated more readily with consequently better drainage when the latter solution was used. Hydrogen peroxide, potassium permanganate, and chromic acid solutions also were used without notable success. Zinc peroxide, arsenicals, and sulfanilamide did not produce strikingly favorable results. The fingers, hand, and arm are then splinted and put at rest in the position of function and whenever possible arranged so that the position will favor dependent drainage. It is our belief that practically without exception cases of this type should be hospitalized. A Wassermann should be done in all patients presenting human contaminated lesions.

As has been stated, the initial injuries in the late infected cases occurring in the region of the knuckle outnumbered those of the fingers. In 34 of the 54 patients the knuckles were involved, 15 occurring over the third metacarpophalangeal joint, the others scattered and of this group of 34 cases, the joint cavity itself was infected in 19 instances. There were 19 cases with lesions of the fingers, 16 injuries being on the dorsal surface, and 3 on the volar surface. In 6 cases the middle interphalangeal joint was infected and in 4 cases the distal interphalangeal joint was involved. As might be expected, partial or complete laceration of extensor tendons occurred in 18 cases and in only 6 cases were the flexor tendons partially severed. There was 1 case presenting a laceration of dorsum of the hand alone.

In several cases there was multiple involvement of joints, fascial spaces, and tendon sheaths. However, in 12 cases infection was confined to the dorsal subcutaneous space and

Fig 13 Severely infected finger. Amputation required

in 21 cases both the dorsal subcutaneous and dorsal subaponeurotic space was infected (Fig 11). Infection of the midpalmar space was present in 3 cases and this seems significant in that this space is not commonly involved in the usual hand infection. In 1 case infection extended from an involvement of the index flexor tendon and its sheath to the thenar space. In another case the ulnar, radial bursa, retroflexor space, and bones of the wrist and hand became so severely infected from a knuckle lesion that amputation through the forearm was required. From an original focus at the metacarpophalangeal joint, infection spread to the lumbrical spaces in 9 cases. Thirteen cases of the total 48 developed stiff fingers and in 5 cases amputation of parts was required, in 1 of which it was necessary to perform amputation through the forearm (Fig 13).

In spite of the severity of these infections, the average length of healing was 34 days and 9.4 was the average number of hospital days. No fatalities occurred in this group of cases.

As has been noted in the literature (6), these infections are prone to recurrence and frequent exacerbations. In our series there were 3 such instances, 1 in 3 weeks, 1 in 2 months, and 1 in 3 years' time.

Fig. Function obtained following drainage of infection of subcutaneous sub-sponserotic and joint spaces.

paper infections of this type when implanted in certain regions may characteristically spread along certain lines to involve adjacent

Fig. Drained infection. Dorsal subcutaneous and dorsal sub-sponserotic space.

or deeper structures. The deepest anatomic plane involved should be inspected, as the infection may spread along the lowermost plane (Fig. 9). Infection of the joint, if adequately drained, does not always result in a completely ankylosed joint as in many instances excellent function is obtained (Fig. 10). An understanding of the pathogenesis of the advance of infection is essential to the correct surgical management of these severe infections, since it is only by locating those areas of greatest potential danger and recognizing the presence of infection that the lesion can be intelligently and satisfactorily managed. One should be slow to amputate extensively infected fingers but extensive drainage of the soft parts is essential. Often a useful part may be preserved or if amputation later becomes necessary more of the extremity may be saved. Amputation should be avoided in the presence of an acute infection.

The wounds are then loosely packed with vaseline gauze and usually massive wet dressings are applied. A considerable variety of antiseptic solutions have been employed. In addition to saline, boric acid and magnesium

INTERSCAPULOTHORACIC AMPUTATION FOR MALIGNANT TUMORS OF THE UPPER EXTREMITY

A Report of Thirty-one Consecutive Cases

GEORGE T. PACK, M.D., F.A.C.S., GORDON McNEER, M.D., F.A.C.S., and
BRADLEY L. COLEY, M.D., F.A.C.S., New York, New York

INTERSCAPULOTHORACIC amputation is an operation devised to remove the entire upper extremity, the shoulder girdle, and its muscular attachments. The operation has been variously designated as "removal of one-half of the shoulder girdle" by von Eiselsberg, "surgical removal of the breast girdle" by Adelman and "extirpation of the arm and shoulder" by Kocher, but it is the term "interscapulothoracic amputation" which the French surgeons, notably Berger, have employed and which now enjoys popular usage.

In the *Anatomy of the Human Body* by W. Cheselden, there is a note and illustration concerning the case of Samuel Wood, a miller, who in 1737 survived a traumatic amputation of an arm and shoulder, caused by an entwined rope attached to the cogs of a mill wheel. Only slight shock was said to have followed this amputation by avulsion. The English surgeon, R. Cumming, has been generally accredited with having performed the first elective operation of this type which was for a gunshot wound, although Halstead maintained that Larrey was the originator of the formal procedure, as it is done today. Dixie Crosby, in 1836, was the first American surgeon to perform a successful extirpation of the shoulder girdle for tumor. In 1837, Musey of Cincinnati did a scapulectomy following a disarticulation of the humerus for sarcoma, the patient survived 30 years.

Until 1881, i.e., before the era of antiseptics, there were 29 recorded interscapulothoracic amputations for various indications, with an operative mortality of 38 per cent.

The technique of the operation was standardized by Berger, and the classical procedure still bears his eponym, in 1887 he described all the previously published cases and added his own experience with the operation, for which his mortality rate was 10.4 per cent. The most important article dealing with this subject in medical literature was written by Buchanan of Pittsburgh, who analyzed all the reported cases prior to the year 1900. At that time the operation was so unusual as to be a surgical curiosity and surgeons were inclined to rush their individual case reports into press before final end-results could be appreciated. Buchanan, by letter and consultation, secured most of the follow-up data on 141 interscapulothoracic amputations which were done prior to the year 1900.

Our analysis of the evolution of this operation, the indications, and contraindications for it, the modifications of techniques employed, and the final end-results achieved will therefore be presented in three parts: (a) A summary of the Buchanan report, which is a thorough analysis of 141 operations done prior to 1900 (Table II). (b) An analysis of 180 additional case reports from the medical literature from 1900 to date (Table III). This would indicate that the operation is done with surprising infrequency. A complete bibliography of 357 references originally appended to this article revealed the fact that the operation is universally done. These references to articles which appeared in Russian, Japanese, Swedish, Dutch, Portuguese, Italian, Spanish, Hungarian, Roumanian, and Polish medical literature have necessarily been deleted from this article because of insufficient space. Russian surgeons as a national group have probably applied this radical procedure more often than others and, moreover, have contributed

Read before the Surgical Section of the New York Academy
of Medicine, October 7, 1938

Since instituting the described management of early human bite lesions, the number of late cases admitted to the hospital have been definitely fewer in number. For a short interval during a change in the resident staff the late infected cases increased and it was found that the treatment of the early cases was not being carried out as outlined.

The careful evaluation of results in the treatment of human bite infections is difficult because of the variations in the virulence of the contaminating organisms and the resistance of tissues. The criterion of the length of stay in the hospital is not a good index of the extent or severity of the infection. These studies have convinced us that good results in the treatment of human bite infections of the hands can be obtained only by attention to details and adherence to surgical principles. Careful cleansing and gentle handling of tissues have reduced our incidence of severe infections and adequate drainage fixation of parts and irrigation are fundamental necessities in the treatment of the late infections.

SUMMARY

1. The prophylactic treatment of early human bite injuries handled under the regi-

men of soap and water cleansing, limited debridement, wet dressings, and splinting is simple and effective the results obtained being superior or equal to those attained when actual or chemical cauterization was utilized.

2. The correct management of the early human bite cases has reduced the number of late infected cases and we feel that prompt and intelligent treatment of the infected cases has definitely reduced the morbidity and number of disabling and deforming sequelae.

3. In dealing with the late infected cases a clear understanding of the mechanism, depth of penetration and degree of injury in relation to the spread of established infection is essential for adequate and correct surgical treatment.

Of the 34 patients with malignant tumors, living and well and remaining under observation, the average post operative survival period was 16 2 months. The distribution of survival periods was as follows:

0-6 mos	16
7-12 mos	3
1-2 yrs	5
2-3 yrs	8
3-4 yrs	0
Over 4 yrs	2

¹Fifty-one of the 180 patients had undergone other operations prior to the interscapulothoracic amputation. Of these 35 patients had 1 operation 7 had 2, 4 had 3, 3 had 4, 1 had 5, and 1 had 6 previous operations. The types of previous operations are listed.

²Of the living patients, 4 had benign tumors (chondromas) and were known to be living and well for 6 months, 7 years, 12 years and 27 years respectively following the interscapulothoracic amputation.

geon's viewpoint. The ultimate psychological effect of this operation on our patients has not been bad, those who are living are apparently happily adjusted to this handicap.

The indications for this operation may be enumerated in the following decalogue:

1 Non-neoplastic conditions, such as extensive trauma with irreparable damage, gunshot wounds, tuberculosis, incurable osteomyelitis. It is not the purpose of this critique to discuss these indications at length.

2 Intractable pain caused by incurable tumors of the shoulder girdle even though metastases to lungs are present. The purpose here is palliation only, in getting rid of a cumbersome, painful, often suppurating extremity (Polosson, Jeanbrau). This indication is not so valid now that intolerable pain in the shoulder and arm can often be controlled by such neurosurgical measures as cervical chordotomy and posterior rhizotomy.

3 All malignant tumors requiring disarticulation of the humerus at the shoulder. The more major procedure in our experience does not require the penalty of a higher operative

some interesting modifications of the operation (Tikhov Sapezhko Ilchenko) (c) A report of 31 personal cases from the bone and mixed tumors services of the Memorial Hospital (Table IV) These 31 unselected, consecutive interscapulothoracic amputations were all done for malignant tumors of the upper extremity and were performed without an operative death

INDICATIONS FOR INTERSCAPULOTHORACIC AMPUTATION

The necessity for performing such a massive, disabling and disfiguring amputation demands a clear conception of the indications, hazards, natural history of the tumor, responsible and possible end results to be achieved. The idea of sacrificing the clavicle, scapula, and arm with their muscular attachments is so repugnant to most patients and repellent to many surgeons, that one of three sequences is apt to follow: The patient refuses with finality all operative aid, or accepts a more conservative though less certain treatment, or eventually agrees after a prolonged interval, during which the disease advances to the stage wherein an operation of desperation is substituted for what was originally an operation of hope. It may be said in all fairness to the operation which is unquestionably well conceived that too few of them are done as carefully planned elective initial procedures and too many are performed as a last resort following one or more recurrences after incomplete or more conservative operations. The indetermination or reluctance of the patient is not a contraindication from the sur-

Scope of these operable cartilaginous tumors were assessed G. C. Hall of Edinburgh removed one weighing 13 pounds and St. Joseph of Montreal removed one which was so acted on circumstance

Fig 9 Case 15 Operative specimen of amputated hand and forearm. Note congenital neurogenic contractures of fingers associated with localized neurofibromatosis of this extremity. Multiple neurosarcomas appeared, first of hand, later of forearm (see cut), later of upper arm and finally of shoulder, necessitating interscapulothoracic amputation.

The arm is then drawn across the body and the posterior flap is outlined by an incision of the skin along the vertebral border of the scapula, which unites with the anterior incision along the lateral axillary border. The arm is then swung back to its original position and the anterior incision is deepened as far as the pectoral muscles. Division of the pectoral muscles now gives an excellent exposure of the brachial plexus. The surface of the plexus is painted with 10 per cent cocaine and/or 2 per cent novocain solution is injected into the nerve trunks. After division of the various

Fig 10 Case 15 To illustrate the anatomical defect and character of the scar. This patient is now living and well more than 6 years following this operation for neurogenic sarcoma.

nerve components of the plexus, the ligated proximal stumps are injected with small quantities of 95 per cent alcohol to lessen the possibility of amputation neuromas and causalgia. The arm is now brought forward again and the muscles of the posterior flap, along the vertebral margin of the scapula, are divided. Care is taken to clamp, sever, and ligate the transverse cervical artery before it retracts, if this has not been done at an earlier stage. With the scapula freed of its muscular attachments, the amputation is complete. The bleeding vessels are ligated with fine silk. The skin can usually be closed with interrupted black silk sutures. It heals with a surprisingly good linear scar. Since the adoption of the silk technique there has been less need for the use of drains. Skin grafting is resorted to in instances in which the size and the location of the tumor and the degree of skin involvement require a greater sacrifice of skin.

The patient is usually able to be out of bed on the third postoperative day and home

Fig. 7. Case 7. Malignant melanoma, primary on the hand with metastases to epitrochlear and axillary lymph nodes and diffuse linear extension by permeation through the arm. Gross specimen shows extent of involvement. The mass in the upper arm is almost microscopically indistinguishable from neurosarcoma.

with preservation of the arm, if involved by chondrosarcoma or osteosarcoma of low grade malignancy.

10 Relatively benign tumors causing symptoms and disability because of their size and location e.g. certain huge chondromas developing in the neighborhood of the shoulder joint.

OPERATIVE TECHNIQUE

A The Classical Berger Operation

The patient is placed on his back with the involved shoulder elevated so that the skin can be prepared by antisepsis well beyond the midline front and back. The corresponding arm is well wrapped from fingers to shoulder and left free and mobile to be held by an assistant. By this means the arm may be held in various positions to facilitate the anterior or posterior dissection of the shoulder. Tourniquets and Wyeth pins are unnecessary.

A linear incision is first made over the middle third of the clavicle and this incision is extended through the soft tissues to the periosteum. The middle third of the clavicle is now resected, usually with a Gigli saw. Through this window the subclavian vessels are exposed with the artery more deeply

Fig. 8. Clinical photograph of type and regional location of tumor suitable for interscapulothoracic amputation. Osteosarcoma developing on base of Peyer's disease of bone, Case (see Table IV).

situated beneath the vein. At this point the modification of LeConte may well be given, as he advocates the resection of the entire clavicle beginning with the sternoclavicular joint, for the avowed reason that this procedure does afford a better exposure of the subclavian vessels, particularly the artery which is to be ligated first, and it enables the operator to recognize and ligate the suprascapular and transverse cervical vessels. This complete claviclectomy does give better exposure and is absolutely indicated if the clavicle is involved by the tumor but it must be admitted that there are greater dangers of air embolism and injuries to the pleural dome and thoracic duct (on the left side).

After exposure of the neurovascular bundle at the base of the neck the subclavian artery is divided between ligatures of heavy black silk and the vein is treated in a similar manner. The proximal stump of the artery and vein are always doubly ligated. The original skin incision is then carried almost to the tip of the acromion after which it is extended downward along the anterior axillary border

Fig 13 Case 19 Left, Ulcerating, fungating neurogenic sarcoma of forearm, treated by amputation through upper arm. Recurrence later developed in the axilla, which was

then treated by interscapulothoracic amputation

Fig 14 Case 19 Character of wound 18 days after interscapulothoracic amputation

merus and then doing the scapulectomy later.

LaFaye did not resect the clavicle, but ligated the axillary vessels and disarticulated the humerus and the scapula from the clavicle.

Kuster added a vertical excision over the sternomastoid muscle to the handle of the racquet incision along the clavicle. He asserted that this gave a better exposure of the subclavian vessels and that it was particularly helpful in permitting primary ligation of the transverse cervical artery and vein.

COMPLICATIONS

Interscapulothoracic amputation is a radical, major, and dramatic operation, but it is really a simple and safe procedure once the subclavian vessels are securely ligated. The exposure of these vessels is occasionally very difficult due to the location of certain bulky tumors which overlie the operative field. In thin-chested individuals, especially when the arm has long been useless, the subclavian vessels as they lie on the first rib must be looked for considerably above the clavicular incision. With the danger of hemorrhage avoided, the patient subjected to this operation is relatively safe. In one of our recent patients, the subclavian vein was accidentally opened during a difficult attempt to free the artery, air was audibly aspirated into the vein, hemorrhage although great was controlled by compressing the vein with a finger against the first rib, and the patient went into shock. He

was restored by immediate transfusion as the vein was repaired and the operator allowed to proceed with the amputation. The patient recovered from this experience without any late complications. One of von Bergmann's patients died from hemorrhage caused by extension of the cancer around the subclavian vessels, this surgeon made a heroic effort to save his patient by tying off the superior vena cava.

Shock is minimal when proper preoperative and sustaining measures are in use, such as blood transfusions, usually given concurrently during the operation using the opposite arm or leg. Due to fixation of the tumor, the pleural cavity may be entered with the complications characteristic of pneumothorax. Injury to the thoracic duct by a left interscapulothoracic amputation may conceivably occur, but we have never seen or read of this occurrence.

CONSERVATIVE OPERATIONS VERSUS INTERSCAPULOTHORACIC AMPUTATION FOR MALIGNANT TUMORS

In the previous listing of indications for interscapulothoracic amputation, the comparative values of this radical procedure with more conservative operations have been considered. The practicability of the irradiation of certain liposarcomas and lymphosarcomas and the dissection of muscle groups containing encapsulated rhabdomyosarcomas and neuro-

Fig. left. Case 6. Roentgenogram of osteosarcoma developing in fractured bone cyst with persistent non-union.

within 2 weeks. One of our patients had such good primary wound healing that she was able to start a 600 mile automobile trip on the ninth day after operation.

B The Anterior or Pectoral Approach of Kocher

The only difficulty encountered during the Berger operation is the exposure of the subclavian vessels. The anterior approach suggested by Kocher avoids this handicap and in our hands has proved to be a welcome modification of the original operation. After the middle third of the clavicle has been resected, the ligation of the subclavian vessels is postponed until the anterior incision is carried through the pectoral muscles into the axilla. This part of the dissection is similar to the same phase in a radical mastectomy as the axillary artery and vein come immediately into view. With the more adequate exposure afforded by enlargement of the operating field the subclavian vessels are more readily located and the underlying artery mobilized and li-

gated without the previous hazard of injuring the overlying vein.

From this point on, the operative technique is exactly similar to that described

C The Posterior or Retroscapular Approach of Littlewood

According to some advocates, particularly Knaggs, the posterior approach of Littlewood may be done with greater speed and more anatomical exactness. After division of the midthird of the clavicle the posterior flap is outlined first and then the scapula is freed from its medial and superior muscular attachments. The supposed advantage of this technique is that when the neurovascular bundle is encountered from the posterior aspect, the subclavian artery appears first the vein second and the brachial plexus last in the exact order desired for ligation and severance.

D Additional Operative Details

Cairo (924) suggested a 2 stage operation in old patients, first disarticulating the hu-

END-RESULTS

In a comparative study of end-results grouped in periods of medical effort, the statistician must carefully analyze the collected data for sources of possible error. For example, the number of long term survivals of patients with "sarcoma" following interscapulothoracic amputation listed in Buchanan's report prior to 1900 is much greater than the number surviving in the series we have collected and which were reported from 1900 to date. The surgical technique, facilities for early diagnosis, and more detailed knowledge of the life history of these malignant tumors have unquestionably improved, and yet the same good end-results are not achieved. The explanation probably lies in correct histological classification and diagnosis, for example, giant cell "sarcoma" of bone is now more commonly referred to as benign giant cell tumor of bone.

Histological type of tumor in relation to age of patient. As the sarcomas which comprise the majority of tumors for which this operation is done, are more common in young adulthood, the average age of 33 years for these patients is what would be expected. Because the operation does not cause much surgical shock, it may be safely done in the case of elderly patients, if there are no other contraindications. The youngest patient was 12 years and the oldest patient was 72 years of age.

The average ages of patients with the different histological types of tumors for which this operation was done was with osteogenic sarcoma, 23 years, with other malignant bone tumors, 48 years, with neurogenic sarcoma, 38 years, with rhabdomyosarcoma, 52 years, with melanoma malignum, 40 years, and with squamous cell carcinoma, 63 years.

Eighteen of the 31 interscapulothoracic amputations were for malignant bone tumors. During the past 6 years, there has been a growing tendency at the Memorial Hospital to perform this operation more frequently for neurosarcomas and rhabdomyosarcomas of the upper arm and shoulder.

Duration of symptoms in relation to histological type of tumor (Memorial Hospital Series). The malignant tumors of the soft

somatic tissues, i.e., neurosarcomas, rhabdomyosarcomas, and soft part sarcomas of undetermined histogenesis, present a longer latent period between the date of the first symptoms and the interscapulothoracic amputation, than do the malignant bone tumors, not because of slower growth or lessened degree of malignancy but because the necessity for a radical surgical procedure does not seem so urgent. Patient and surgeon alike are more content to temporize with conservative measures if the sarcomas do not involve bone. Primary or immediate interscapulothoracic amputation is more likely to be acceptable and to be done for malignant tumors of bone than for sarcomas of the soft somatic tissues. For example, the duration of symptoms before this operation for the various histological types of tumors was for osteogenic sarcoma, 6 months, for other malignant tumors of bone, 4 months, for neurogenic sarcoma, 60 months, for rhabdomyosarcoma, 16 months, for other soft part sarcomas, 25 months, for squamous cell carcinoma, 36 months, and for malignant melanoma, 3 months.

Type of previous operation (Memorial Hospital Series). In our experience, the formal incisional biopsy of sarcomas is a dangerous operation and from the viewpoint of prognosis should almost be considered a major procedure. The so called local excisions of soft part sarcomas, as performed at the Memorial Hospital, are not enucleations but radical dissections with sacrifice of normal tissues surrounding the neoplasm. Thirteen, or 42 per cent, of our 31 patients had undergone previous operations, such as formal incisional biopsy, 5, local excision, 1, 2 excisions, 1, 3 excisions, 1, 5 excisions, 1, 7 excisions, 1, and lesser amputations, 2.

Type of operative technique (Memorial Hospital Series). Twenty-one of the interscapulothoracic amputations were done according to the Berger classical procedure. The 10 remaining operations were performed chiefly during the past 5 years by the Kocher anterior and pectoral approach which will undoubtedly gain favor because it can be performed with greater ease and safety.

Effect of preoperative irradiation on end-results (Memorial Hospital Series). Of the

sarcomas of low grade malignancy is recognized. One of us (B. L. C.) has published a series of case reports of scapulectomy for malignant tumors the osteochondrosarcomas of this bone may attain a large size without metastasizing. Although this operation has proved successful in the hands of some surgeons the cases should be properly selected. In an unbiased study of 65 malignant tumors of the scapula, Vancrède reported that not one patient had been cured by conservative measures.

In selecting one of these more conservative procedures such as scapulectomy or disarticulation of the humerus, the surgeon should do so with the firm belief that it is wholly sufficient as far as the local tumor is concerned and not because he relies on another opportunity for local cure through a secondary or subsequent interscapulothoracic amputation. (Table I)

The Tikhor-Lsberg operation. An operation planned by the Russian surgeon Tikhor and applied afterward by Bauman and Lsberg has for its purpose the excision of the scapula, clavicle and head of the humerus with preservation of an extremity which functions slightly. A racquet incision is made along the clavicle and the pectoral muscles are divided. The brachial nerve plexus and the subclavian artery and vein are dissected free and spared. A circular incision around the humerus determines the lower level of the resection and the humerus is sawed through. By a posterior incision over the scapula, this bone together with the clavicle and upper segment of the humerus is sawed through. By a posterior incision over the scapula, this bone together with the clavicle and upper segment of the humerus is resected. The biceps and triceps muscles are sutured to the intercostal muscles anteriorly and posteriorly. At the completion of the operation the lower arm, forearm, and hand are intact, and the functions of the forearm and hand are partly retained but of course shoulder and upper arm movements are no longer possible. A study of the case reports of this operation lends support to the belief that it is palliative only because the patients who have not died have required subsequent operations for recurrences.

ADVANTAGES OF INTERSCAPULOTHORACIC AMPUTATION OVER DISARTICULATION FOR MALIGNANT TUMORS OF THE UPPER ARM

The following advantages of interscapulothoracic amputation over disarticulation for malignant tumors of the upper arm may be mentioned

- 1 The lymphatics and veins are removed at a much higher level.

- 2 The shoulder muscles with their natural fascial planes are entirely removed which is especially important if the tumor has shown invasive tendencies

- 3 The more radical operation not only permits dissection of the axilla but a removal of the axillary boundaries

- 4 The mortality is no greater. The 31 consecutive interscapulothoracic amputations reported in this article were done without an operative death which is proof enough of the safety of this operation

- 5 The wounds resultant after interscapulothoracic amputation heal more satisfactorily as there are practically no dead spaces to be obliterated.

- 6 The deformity is greater but not enough to be a deciding factor

- 7 Interscapulothoracic amputation is often done for a malignant tumor recurrent in the stump of the disarticulation. This very fact would indicate that the original disarticulation had not been wisely chosen as the proper operation. Consecutive operations finally terminating in interscapulothoracic amputation appear in every reported series, including our own (see Cases 15, 19 and 29 in Table IV). A patient with a neurosarcoma or fascial sarcoma of the hand, wrist, or forearm relates a history of one or more local excisions with recurrences developing each time proximal to the scar finally amputation of the forearm, later of the arm and still later disarticulation of the humerus may be done for proximally recurring tumors usually with increasing degrees of malignancy. Yet in retrospect for each individual patient in whom this series of events occurs, few surgeons would advise so radical a primary procedure as interscapulothoracic amputation for a sarcoma originating for example, in the forearm

TABLE IV—INTERSCAPULOTHORACIC AMPUTATIONS PERFORMED AT THE MEMORIAL HOSPITAL, NEW YORK, 1924-1940—Continued

patients surviving at the time of this report, 2 who had no preoperative irradiation are clinically well for 11 and 67 months, respectively after the operation. Five patients who had preoperative irradiation are living: 1 with metastasis 4 months later and 4 without clinical evidence of recurrence for 20, 30, 60 months, respectively. Rocher and Papon assert that preliminary irradiation permits later interscapulothoracic amputation but no case reports were presented to support this contention. The application of irradiation as a means of avoiding this major amputation is a different matter entirely from the selective use of irradiation as a preoperative measure. It is different to evaluate the benefits of such therapy and it certainly cannot be done by a study of our own end-results, because we have been so liberal in giving x-ray and radium therapy to these patients. One would think

that interscapulothoracic amputation would suffice as the sole treatment if the line of incision were well above the upper limits of the tumor and that any preoperative adjuvant measures would be superfluous. Nevertheless, our past experience in dealing with sarcomas of the soft somatic tissues of other regions has indicated that there is greater freedom from local recurrence and distant metastases if preliminary irradiation is given. This is especially true for the liposarcomas. The reason for this is hard to fathom unless it could be that the trauma which is associated with the operation causes immediate dissemination of metastases; the lethal or abiotic action of the preliminary x-ray or radium therapy could conservably lessen this hazard.

Patients living at the time of report (Table V). Of the osteogenic sarcoma group 2 patients were without disease 60 and 67 months, respectively, of the neurogenic sarcoma group 3 were without disease 11, 30 and 60 months, respectively, of the soft part sarcoma (undetermined histogenesis) group 1 was without disease 12 months and of the rhabdomyosarcoma group 1 was living with recurrence and pulmonary metastases, 4 months. The patient with squamous cell carcinoma lived 9 years without evidence of recurrence or metastasis and then died of apoplexy.

in these experiments should be quite similar to those expected in man. The bacteriology of our experiments is summarized in Table I. Plain agar, blood agar, Endo's agar and anaerobic brain-heart infusion broth were routinely inoculated, and transfers to the various sugars were made as necessary to identify the individual organisms. The high incidence of *Clostridium welchii* leads one to the conclusion that had therapeutic serum been used, the mortality rate could have been lowered appreciably. This was the original intention of the authors, but Army reserve commissions interrupted the study (Table I).

There were 5 groups of 10 dogs each, 1 group of 12 dogs, and 1 group of 8 dogs. The results are tabulated in Table II and discussed more fully under individual experiments. The larger number of dogs in the bacteriological table is explained by the fact that many dogs died within 24 hours or that their wounds drained spontaneously and thus were discarded from the reported groups (Table II).

EXPERIMENT I

A control group of 10 dogs was established with a mortality rate of 100 per cent. This group consisted entirely of adult dogs whose wounds did not drain and who survived more than 24 hours. Dogs dying within 24 hours would not allow time for treatment and were, therefore, unsatisfactory for other experiments.

Dogs in this group were given food and water, as in all groups, but received no treatment. The wounds were opened in 24 hours for culture and then the mattress sutures were tied. These dogs all developed signs and symptoms of generalized peritonitis, characterized by leucocytosis, elevation of temperature, vomiting, and abdominal rigidity and tenderness. The average duration of life was 41.4 hours, most of the dogs died at 36 hours.

The standards agreed upon in the selection of this group were rigidly adhered to in all of the following experiments.

EXPERIMENT II

A group of 10 dogs was used in which treatment was started within 18 hours by an 0.8 per cent solution of sulfanilamide subcutaneously. One daily dose of 0.14 grams per kilo-

gram of body weight was given in small amounts over the neck and back. Care was used not to overdilate the tissues in any one area, but in spite of this, most of the surviving animals developed skin sloughs. The average sulfanilamide blood level was 6.0 milligrams per cent and the highest obtained was 16.0 milligrams per cent. Of the dogs not surviving the experiment, the average duration of life was 55 hours. Autopsy showed no gross evidence of damage to the liver or kidneys but did show cloudy purulent peritoneal fluid and redness of peritoneum. The 5 surviving dogs (50 per cent) killed and subjected to postmortem examination later, showed only a few adhesions to the cecum and lateral wall.

EXPERIMENT III

Sulfanilamide (0.8 per cent solution) was administered intraperitoneally in 2 doses daily totaling 0.07 grams per kilogram of body weight. The dosage was reduced to 0.07 grams per kilogram of body weight because the first group of dogs given a dose of 0.14 grams per kilogram of body weight all expired within a few hours. Autopsy, however, failed to reveal any reason for the rapid death.

The drug was administered through a large bore needle which was found most convenient for these animals. Tubes sutured in place were pulled out by the animals, and drainage tracts resulted.

In this group the mortality rate was 50 per cent with an average survival of 58 hours. The

TREATMENT OF PERITONITIS

Intraperitoneal Use of the Sulfonamides Based Upon Animal Experiments

C. H. EPPS, M.D. E. B. LEY, M.D. and R. M. HOWARD, M.D., F.A.C.S.
Oklahoma City, Oklahoma

THE bacteriostatic effect of the sulfonamides¹ is a well established fact in the mind of the clinician and the ever increasing literature serves to signify that this mode of action has a sound experimental basis while the details of its inhibitory effect are still in the theoretical stages.

In a very comprehensive article, Lockwood advances a hypothesis which supplies a theoretical framework upon which a complete scheme of sulfonamide chemotherapy may be constructed. He specifies the following 3 principal factors which should tend to modify the curative effect of the sulfonamide compounds: (1) concentration of the drug maintained in the immediate environment of the bacteria; (2) the mobilization of cellular defenses; (3) concentration of sulfonamide inhibitor substances. It is with the first factor that we find our chief interest in this experiment.

It is reasonable to believe that if the local concentration of the drug can be immediately elevated and maintained at the site of action of the invading organism or at an anatomical or pathological point, the chances for a favorable outcome should be greatly superior to a route of administration which primarily promotes an elevated concentration systemically.

As to the ability to kill beta hemolytic streptococcus *in vitro*, Colebrook, Buttle and O'Meara have definitely shown no essential difference between sulfanilamide laden blood from a treated patient and chemically treated blood from a normal individual.

Many workers (3-7-9) in various fields have endorsed the drugs as valuable for their local effectiveness. During the past year the attention of many abdominal surgeons has been

drawn to the possibilities of intraperitoneal use of the sulfonamides in the treatment of peritonitis. Thompson, Rosenberg, Dees, and others have reported the intraperitoneal use of crystalline sulfanilamide in the treatment of appendiceal peritonitis. It has been our experience from clinical and necropsy findings that powdered material in the peritoneal cavity is quickly walled off by omentum and is ultimately dependent upon absorption and systemic concentration for its local effect.

We have carried out a series of animal experiments in which we attempted a comparative study of the sulfonamides in solution or suspension by the systemic and local routes of administration.

In order to study this problem, it was necessary to produce an experimental appendiceal peritonitis comparable to that in man. The method described by Bower, Burns and Mengle (1) was used. The mesentery and base of the appendix were ligated and a large dose of castor oil was given to produce perforation and generalized peritonitis.

The wounds were sutured in layers, a small opening being left at the upper end where a through and through mattress suture was left untied. After 12 to 8 hours, the skin was prepared with iodine and alcohol and a sterile sponge forceps was introduced into the peritoneal cavity and rotated in a stirring motion to insure a generalized spread of the infection, and to a certain extent simulate the spread and trauma associated with the operation. Sterile applicators were then inserted for cultures and the mattress sutures were tied. Postmortem cultures were not taken because usually the animals had been dead an hour or two before being discovered.

As shown by Bower, Burns, and Mengle (2) the bacteriology is strikingly similar in man and dog and therefore, results obtained

From the Department of Surgery, Oklahoma State University Hospital.

There were 5 groups of 10 dogs each, 1 group of 12 dogs, and 1 group of 8 dogs. The results are tabulated in Table II and discussed more fully under individual experiments. The larger number of dogs in the bacteriological table is explained by the fact that many dogs died within 24 hours or that their wounds drained spontaneously and thus were discarded from the reported groups (Table II).

EXPERIMENT I

A control group of 10 dogs was established with a mortality rate of 100 per cent. This group consisted entirely of adult dogs whose wounds did not drain and who survived more than 24 hours. Dogs dying within 24 hours would not allow time for treatment and were, therefore, unsatisfactory for other experiments.

Dogs in this group were given food and water, as in all groups, but received no treatment. The wounds were opened in 24 hours for culture and then the mattress sutures were tied. These dogs all developed signs and symptoms of generalized peritonitis, characterized by leukocytosis, elevation of temperature, vomiting, and abdominal rigidity and tenderness. The average duration of life was 41.4 hours, most of the dogs died at 36 hours.

The standards agreed upon in the selection of this group were rigidly adhered to in all of the following experiments.

EXPERIMENT II

A group of 10 dogs was used in which treatment was started within 18 hours by an 0.8 per cent solution of sulfanilamide subcutaneously. One daily dose of 0.14 grams per kilo-

gram of body weight was given in small amounts over the neck and back. Care was used not to overdilate the tissues in any one area, but in spite of this, most of the surviving animals developed skin sloughs. The average sulfanilamide blood level was 6.0 milligrams per cent and the highest obtained was 16.0 milligrams per cent. Of the dogs not surviving the experiment, the average duration of life was 55 hours. Autopsy showed no gross evidence of damage to the liver or kidneys but did show cloudy purulent peritoneal fluid and redness of peritoneum. The 5 surviving dogs (50 per cent) killed and subjected to postmortem examination later, showed only a few adhesions to the cecum and lateral wall.

EXPERIMENT III

Sulfanilamide (0.8 per cent solution) was administered intraperitoneally in 2 doses daily totaling 0.07 grams per kilogram of body weight. The dosage was reduced to 0.07 grams per kilogram of body weight because the first group of dogs given a dose of 0.14 grams per kilogram of body weight all expired within a few hours. Autopsy, however, failed to reveal any reason for the rapid death.

The drug was administered through a large bore needle which was found most convenient for these animals. Tubes sutured in place were pulled out by the animals and drainage tracts resulted.

In this group the mortality rate was 50 per cent with an average survival of 58 hours. The

TABLE II.—COMPARATIVE STUDY OF SULFONAMIDES IN THE TREATMENT OF EXPERIMENTALLY PRODUCED APPENDICEAL PERITONITIS IN DOGS

Experiments	Number of dogs	Number of deaths	Number of recoveries	Mortality per cent
I Control				100
II Sulfanilamide subq. 0.4 gm./kg		5	5	50
III Sulfanilamide, intraperitoneally 0.7 gm./kilogram daily divided doses		5	5	50
IV Sulfanilamide, intravenously 0.4 gm./kilogram daily divided doses		8		80
V Sod. Sulfapyridine, intraperitoneally 0.7 gm./kilogram daily divided doses		6	6	50
VI Sulfathiazole, intraperitoneally 1.4 gm./kilogram daily		4	6	40
VII Sulfabenzamide, intraperitoneally 1.4 gm./kilogram daily	8	7		87

highest blood level observed was 12 milligrams per cent, the average being 2.8 milligrams per cent. The peritoneal cavity of the dogs succumbing to the infection contained dark, greenish brown purulent fluid, sloughed appendices but no leakage from the cecum. The surviving dogs killed 2 weeks after cessation of treatment showed normal peritoneal cavities except for a moderate amount of free fluid which, in 2 cases was definitely bloody. The liver and kidneys were grossly normal.

EXPERIMENT IV

This group was treated with sulfanilamide (0.8 per cent solution) intravenously in 2 doses daily totaling 0.14 grams per kilogram of body weight. The mortality rate was 80 per cent with an average survival of 48.5 hours. The average blood level was 4.0 milligrams per cent.

The autopsy findings in this group were not significantly different from those of Experiment II.

EXPERIMENT V

Sodium sulfapyridine, 1 per cent solution was given this group of animals intraperitoneally in 2 doses daily totaling 0.07 grams per kilogram of body weight. The mortality rate was 50 per cent average survival 46 hours. The blood level in all the dogs 12 hours after dosing was below milligram per

cent. All dogs not surviving the experiment showed purulent fluid and generalized peritoneal inflammation. One abdomen contained a large amount of bloody fluid. Of the survivors, 2 showed very small omental abscesses (1 to 5 c.cm.) whereas the 3 others had normal peritoneal cavities with very few adhesions. No gross liver or kidney damage was observed in either group.

EXPERIMENT VI

Sulfathiazole being somewhat less soluble than the other sulfonamides, was given in 1 per cent solution and suspension, and it was so well tolerated that 2 doses daily totaling 0.14 grams per kilogram of body weight were given. The mortality of this group was 40 per cent the average survival time, 38 hours. The average sulfathiazole blood level was 4.3 milligrams per cent with 22.9 milligrams per cent the highest observed.

Postmortem examinations on death showed generalized peritonitis and purulent fluid. The appendices were sloughed in all cases yet the ligatures at the cecum held. Of the 6 surviving dogs killed 1 week later 2 had 300 to 500 cubic centimeters of bloody fluid with an injected peritoneum. The 4 other surviving dogs had very small omental abscesses containing about 5 cubic centimeters of purulent exudate at the ileocecal juncture. Otherwise, the peritoneum was normal.

EXPERIMENT VII

In this group sulfabenzamide (4 N-caproamidobenzene-sulfonhydroxamide) was dissolved in one tenth normal sodium hydroxide and neutralized with normal lactic acid. The resultant 1 per cent solution was nonirritating and according to Moore et al. is caproylamino-benzene-sulfonic acid which is thought by other observers to retain some therapeutic activity. Eight dogs were treated in this group by 2 intraperitoneal doses daily totaling 0.14 grams per kilogram of body weight. Seven, 87 per cent, of the 8 dogs died having 57 hours as an average survival time. The 12 hour blood levels in these dogs were all below 1 milligram per cent. The drug itself was not considered responsible for the deaths, as twice this dosage was given intraperitoneally as a single dose to normal animals with no apparent bad effects.

The necropsy findings of the succumbed animals were those of generalized peritonitis. Autopsy on one surviving dog showed only a few adhesions in the region of the cecum. Although the mortality rate does not speak well of the therapeutic efficacy of this drug, the experiment does eliminate the possibility of any of the animals in other experiments being saved by parenteral fluids rather than from specific action of the drugs administered.

ANALYSIS OF STUDY

The primary intention of this experiment was to determine the therapeutic value of the sulfonamides when applied locally in the treatment of peritonitis. Sulfanilamide was used as a standard to develop a safe and effective route of administration. The results as tabulated in Table II would seem to indicate that subcutaneous or intraperitoneal administration is preferable to the intravenous method. This is best explained by the relatively short action of the drug when given by the intravenous route.

Of the 4 drugs used intraperitoneally, sulfathiazole seems to be the most effective. This may in part be due to the fact that part of the drug was given in suspension which provided a longer time of action before complete absorption took place. We fully realize that the number of dogs in each group is too small for positive and definite conclusions, but we are certain that any one of the sulfonamides may be administered intraperitoneally with safety and without deleterious effect to the peritoneum or intraperitoneal organs. The usual toxic manifestations, of course, must be anticipated and treated appropriately if they arise.

Sulfanilamide intraperitoneally in the treatment of peritonitis seems definitely and unquestionably of value as proved by Mueller and by Jackson. In all of these cases, the drug was given in powder form. This necessitated a large initial dose, and any indicated subsequent intraperitoneal therapy with powder was difficult or was restricted to some other form and route of administration. Sodium sulfapyridine has been used intraperitoneally in a 4 per cent solution in 10 cases at The Oklahoma University Hospitals. The results

have been spectacular and the ease of administration remarkable. It can be given through the drainage tube in small divided doses or larger single doses, or by a continuous drip method, and repeated checks on the blood level can dictate the necessary dosage. In none of the cases in which the drug was given only by the intraperitoneal route were serious toxic manifestations encountered. There is evidence to indicate that combined therapy may be more hazardous.

CONCLUSIONS

- 1 Sulfanilamide, sodium sulfapyridine, or sulfathiazole may be administered intraperitoneally in solution or suspension in proper dosage, with no deleterious effect.

- 2 Intraperitoneal use of the sulfonamides is effective in the treatment of peritonitis.

- 3 Of the three sulfonamides, sulfathiazole appears to be the most effective in the local treatment of peritonitis.

- 4 Subcutaneous administration of sulfanilamide frequently resulted in skin sloughs.

- 5 Proper dosage is essential. The usual toxic manifestations may be expected and treated appropriately.

The authors wish to acknowledge the splendid cooperation of Ida Lucille Brown Wallace, instructor in the Department of Bacteriology, University of Oklahoma School of Medicine, who made the bacteriological studies in this experiment.

RETROCECAL APPENDIX

Its Diagnosis and Surgical Approach

WILLIAM T HARSHA, M.D. F.A.C.S. Chicago, Illinois

THE single definite diagnostic feature of retrocecal appendicitis is a vertical line of tenderness starting at the iliac crest, 6 to 8 centimeters behind the anterior superior spine and extending vertically upward, the distance of the involved appendix, often to the rib margin.

The intensity of the initial symptoms is modified by the position. Both pain and vomiting are initially slower in their development and less intense in character. The appendicitis syndrome from the appendix situated retroceally can be compared to the syndrome of obstructive lesions of the lower bowel. The clinical picture of high bowel obstruction is similar to the freely placed acute appendicitis, while retrocecal appendicitis presents a clinical picture similar to that of lower bowel obstruction. Some systematic differential plan, as suggested by Sloan¹ should be borne in mind in confirming the general diagnosis of appendicitis before the search for localization is begun.

The following method of approach permits the removal of a retrocecal appendix with a minimum amount of contamination of the peritoneal surface.

The incision is made parallel to and about 3 centimeters lateral to the outer rectus margin, starting about 8 centimeters above the level of the umbilicus and following the outer margin of the rectus abdominis down to the level of the internal pillar of the external abdominal ring. This incision is curved with the convexity directed outward. The incision is carried down to the fascia of the external oblique; the fascia is exposed for the entire length of the skin incision (Fig. 1).

At the level of the anterior superior spine of the ilium and about 1 centimeter lateral to the border of the rectus muscle, the external oblique aponeurosis is incised vertically and

this incision is extended upward and downward to the limits of the skin incision (Fig. 2). The fibrous aponeurotic margins of the external oblique separated by the incision are held by hemostats as landmarks in closure (Fig. 3).

The internal oblique and transversus muscles are separated by blunt penetration with scissors to the preperitoneal fat, then by hooked digital retraction directed upward and downward are separated horizontally in the direction of their fibers, thus exposing the outer surface of the peritoneum and the preperitoneal fat. The under surface of the transversus muscle is now separated from the peritoneum below to the level of the inguinal ring above to the upper level of the incision, medially the peritoneum remains in its normal anatomic relation, but laterally and posteriorly from the iliac fossa, from the tip of the iliac crest around the posterior surface of the cecum, reaching medially to the level of the ureter so that the cecum can be mobilized and the posterior wall can be elevated and rotated anteriorly and medially.

Palpation of the posterior wall of the cecum now discloses the tumor of the inflamed appendix (Fig. 3). Turning the cecum anteromedially directing the posterior wall anteriorly and retracting outside the peritoneum (the overlying small bowel) access may now be had to the peritoneum overlying the diseased area (Fig. 3). The peritoneum is intact until this next step.

Fig 1

Fig 2

Fig 3

Fig 4

Fig 5

Fig 6

This peritoneum is now incised and the appendix is permitted to extrude itself. It can be gently aided if needed (Fig. 4). The presence of fecaliths with necrosis of the wall of the appendix in this position necessitates extreme care in handling at this point, as the appendix in this position is often friable (Fig. 5).

If an abscess cavity of limited area exists around the posterior cecal wall, the anterior margin of the peritoneum may be sutured to the posterolateral cecal wall or to the lateral cecal wall, exteriorizing from an abdominal point of view the infected area. If necrosis of the posterior wall of the cecum has occurred, it should be inverted by sutures. Into this area a Mikulicz drain is placed through a lumbar stab wound. The closure of this perito-

neum is otherwise without drainage, and the wound is closed in layers with sutures of catgut.

SUMMARY

Acute retrocecal appendicitis may be recognized clinically by a vertical line of tenderness extending upward from the iliac crest, 6 to 8 centimeters posterolateral to the anterior superior spine, to the tip of the appendix, often below the rib margin.

The clinical course is often slower in development than other types, due to the relative absence of peritonitis.

A surgical approach to this retrocecal appendix which has proved of advantage is described.

This peritoneum is now incised and the appendix is permitted to extrude itself. It can be gently aided if needed (Fig 4). The presence of fecaliths with necrosis of the wall of the appendix in this position necessitates extreme care in handling at this point, as the appendix in this position is often friable (Fig 5).

If an abscess cavity of limited area exists around the posterior cecal wall, the anterior margin of the peritoneum may be sutured to the posterolateral cecal wall or to the lateral cecal wall, exteriorizing from an abdominal point of view the infected area. If necrosis of the posterior wall of the cecum has occurred, it should be inverted by sutures. Into this area a Mikulicz drain is placed through a lumbar stab wound. The closure of this perito-

neum is otherwise without drainage, and the wound is closed in layers with sutures of catgut.

THE TONUS OF THE UTERUS DURING PREGNANCY AND ITS RELATION TO LABOR

A Study of 1028 Observations Made With the Lóránd Tocograph

DOUGLAS P MURPHY M.D. F.A.C.S., Philadelphia, Pennsylvania

OBSTETRICIANS have paid little attention to the hardness or tonus of the human uterus that is present between the intermittent contractions which occur during pregnancy. This has been due chiefly to the lack of a suitable means for measuring it. The development of the tocograph (1) however has supplied such a need. It has demonstrated that tonus varies from patient to patient at identical periods during pregnancy as well as in the same patient at different times.

It need hardly be mentioned that the character of labor varies likewise from patient to patient, and it is equally well known that we do not possess, at the present time, any means for predicting what the nature of the labor may be. These facts raised the question as to whether there might not be a significant correlation between the tonus of pregnancy and the character of the labor. If such were the case the information resulting from a consideration of the relationship would have definite practical value and if not a study of tonus would at least throw some light upon a little understood characteristic of uterine physiology.

In previous communications (2, 3) we reported upon the variations in the tonus of the uterus which occur during pregnancy and labor. These observations were relatively few in number. Since they were published additional ones have been made, which include the recording of some unusually high degrees of tonus. These facts together with our desire to determine the exact relation between pregnancy tonus and the character of labor have led to the present re-examination of all of our available material.

MATERIALS AND METHODS

The observations were made between August, 1938 and April 1942 upon patients attending the Maternity Department of the Hospital of the University of Pennsylvania, and ones residing in a private maternity home in Philadelphia.

Measurements of tonus were secured with a Lóránd tocograph which has been described fully elsewhere (1). In brief however it is a mechanical kymograph which registers uterine movements through the medium of the abdominal wall.

Tonus is measured in the following manner. The clockwork of the tocograph is started, and the recording pen is allowed to draw a base line upon the recording paper before the machine is placed upon the patient. With the latter in the supine posture the tocograph is then placed upon the most prominent part of her abdomen.

If the uterus is relatively soft when the tocograph is placed upon the abdomen, the button projecting from the bottom of the machine buries itself full length in the abdominal wall, and thus the recording pen connected with the button fails to be dislodged from its base line position. Under these conditions, the patient is classified as exhibiting no increase in tonus (Fig. 1 226). Above a certain yet unknown, degree of uterine tonus, the tocograph button meets sufficient resistance in the abdominal wall to displace it into the machine, thus dislodging the recording pen from its base line position. Under these conditions, the patient is classified as exhibiting an increase in tonus (Fig. 1 1273). The amount of the latter is estimated in terms of the distance traversed by the pen under extreme circumstances this may reach a maximum of 25 millimeters. For a more detailed consideration of the condition represented by the term tonus, the reader is

shift of base line at these points Tonus nonmeasurable Tracing 1273, patient a tripara Record made day before onset of labor Tocograph placed on abdomen at A and removed at B Note elevation of base line between these two points Tonus measurable and quite high (13 mm)

referred to the evaluation which appears at the end of this report

RESULTS

A group of 435 patients supplied a total of 1,028 tocographic records These were secured from the 79th day of pregnancy to the day before labor, inclusive The number of records per individual appears in Table I The observations are presented under two headings (1) "Tonus in Relation to Pregnancy," and (2) "Tonus in Relation to Labor"

Tonus in relation to pregnancy In a selected group of individuals recordings were made at regular intervals Table II shows the incidence of tonus and its degree in 15 patients who were observed at weekly intervals throughout the 9 or more weeks immediately preceding labor A measurable increase in tonus occurred rarely before the 33rd week of gestation, even after that time, both the incidence and degree varied widely Patient 14 registered no increase at any time before the onset of labor In contrast to her, patient 6 exhibited measurable tonus as early as the 30th week, and practically every week thereafter Patient 4 showed no tonus until the last week of gestation

The presence of measurable tonus at any one time was no indication that it would be found at the time of subsequent recordings, though such was more likely to be the case These data emphasize the variability with which a measurable increase in tonus appears in the same person from week to week, and in different persons at the same period of gestation

In an unselected group of individuals recordings were made at irregular intervals (Tables III, IV, and V)

The influence of advancing pregnancy upon the incidence of a measurable increase in tonus is given in Table III which lists the percentage of tocographic tracings registering a measurable amount of tonus, arranged according to gravidity and to the time in pregnancy that they were secured This degree of tonus was observed in primigravidas as early as the 6th lunar month of pregnancy, but not until the 7th month in the case of multigravidas Primigravidas exhibited their first significant increase in the incidence of measurable tonus, during the 8th month, whereas multigravidas did not do so until one month later During the 10th lunar month, 58.6 per cent of tracings of primigravidas showed an increase in tonus, in contrast to 37.9 per cent of observations upon multigravidas Thus, only 48.4 per cent of tracings of primigravidas and multigravidas combined, recorded a measurable increase in tonus during even the last month of gestation

The influence of advancing pregnancy upon the degree of increase in tonus is recorded in Table IV which shows the average and maximum amount of tonus observed in the tracings of those patients who exhibited a measurable increase in tonus The degree of tonus increased progressively as pregnancy ad-

Table V Showing the influence of the last 14 days of pregnancy upon the incidence and degree of measurable tonus as observed in 451 tocographic tracings. Note (a) Relatively constant occurrence of measurable tonus, (b)

the slight but gradual increase in degree of tonus, (c) the absence of any abrupt change in tonus, (d) the absence of any effect of gravidity upon either characteristic

gives (a) the number of tocographic tracings made during the last 14 days of pregnancy, (b) the number of these which registered a measurable increase in tonus, and (c) the average increase in the latter group. The data in this table indicate (a) the marked variability in the incidence of measurable tonus at this time and also (b) the similar variability in the degree of increase. Furthermore, they show that no sudden change in either characteristic takes place at this time, although there was a tendency for the tonus to become stabilized during the few days immediately preceding labor.

Tonus in relation to labor. Table VI shows the influence of tonus, registered during the last 4 weeks of pregnancy, upon the duration of labor of primigravidas. Each record represented a different patient, no individual exhibited any evidence of cephalopelvic disproportion, all deliveries were vaginal, the infants had cephalic presentations and weighed between 2,500 and 3,500 grams at birth.

The data in the two left-hand columns of Table VI were supplied by patients exhibiting no measurable increase in tonus. Patients who registered a measurable increase supplied the information in the right-hand columns.

The average duration of labor of the patients whose tonus was above the average of those who exhibited measurable tonus did not differ significantly from that of the patients who recorded no measurable tonus at the same periods of pregnancy, respectively.

Table VII shows the influence of tonus, upon the duration of labor of multigravidas. As in the case of primigravidas, the amount of tonus present during late pregnancy had no influence upon the duration of labor.

As to the influence of an unusually high tonus during the last week of pregnancy upon the duration of labor the following is recorded. Eight primigravidas experienced an unusually high degree of tonus (10 to 17 millimeters). One (tonus 15 millimeters) gave birth to a 4,500 gram infant by forceps after a prolonged

Table VII. Showing the average duration of labor of group of multigravidas from whom tocographic records were secured during the last 4 weeks of pregnancy arranged according to whether measurable tonus was absent or above the average in the group that exhibited measurable tonus. Note that the average duration of labor was shorter in the group which recorded no measurable tonus. Compare with data in Table VI.

second stage. Another with a tonus of 17 millimeters was delivered by cesarean section on account of cephalopelvic disproportion and primary inertia. A third patient had a breech delivery. The 5 remaining delivered spontaneously only 1 having a slightly prolonged second stage.

Five multigravidas also registered an unusually high degree of tonus (10 to 13 millimeters) during the last week of pregnancy. The labors of all were short, no second stage lasted longer than 45 minutes, 3 of the deliveries were precipitous.

There was no evidence to indicate that the high tonus of any patient influenced adversely the course of labor. If it had any appreciable effect whatever it aided rather than retarded delivery.

EVALUATION OF STUDY

The present observations indicate that, within certain limits, tonus can be measured with a satisfactory degree of accuracy during pregnancy. This statement is based upon (a) repeated observations upon the same individual at intervals of hours, days, weeks and months and (b) by comparing repeated ob-

servations upon one individual with those of another. Uniform results have been secured from individuals who varied considerably both in weight and in the thickness of their abdominal walls. In carrying out the measurement the tocograph usually is placed in the midline and above the umbilicus, where the abdominal wall is relatively thin and in close contact with the upper pole of the uterus. Furthermore, the registering of the tonus is not influenced by the tightness of the belt which holds the tocograph in position, since varying this factor has no influence upon the measurement.

Although the method of measurement is satisfactory it is not fully established as to just what is being measured. Wolf who has compared measurements made with intra-uterine bags with those secured by external hysterography concludes that the latter records the hardness of the uterine wall rather than intramembranous pressure. The present author concurs in this belief. Whichever characteristic the measurement represents, it is certainly only relative, but nevertheless useful as a means for comparing one patient with another.

It is apparent that tonus varies considerably during pregnancy, but no evidence is forthcoming as yet to explain why these variations occur

It is an interesting observation that a measurable increase in tonus occurs earlier in primigravidas than in multigravidas, and that more of the former experience it throughout pregnancy than do the latter. On the other hand, the degree of tonus attained at the end of pregnancy appears to be the same in primigravidas as in multigravidas. One might expect it to be higher in primigravidas at this time, in view of the fact that it appears earlier and more often in them than it does in the multigravidas.

There appears to be an unusual increase in the incidence of measurable tonus during the 8th lunar month of pregnancy, but no significant change in it during the 2 weeks immediately preceding the onset of labor. It follows from this that knowledge of the degree of tonus present just before labor is of no aid in predicting the time of onset of labor. Nor has any evidence come to light to indicate that a study of tonus alone is of any value in predicting the quality of the uterine activity at the time of labor.

The methods employed in securing the present data have their obvious limitations. These include the fact that the tocograph has the inherent weakness of any precision instrument operated by a spring, that the present observations were made by several different individuals, who employed a number of different tocographs. It is believed, however, that some of the difficulties encountered are outweighed by the number of observations made.

SUMMARY AND CONCLUSIONS

1 A series of 435 patients supplied 1,028 tocographic records of what, for want of a better term, may be described as uterine tonus during pregnancy.

2 Detectable increases in tonus were observed first in primigravidas during the 6th lunar month, and not until the 7th month in the case of multigravidas.

3 Wide variations in tonus were observed in the same patient at different times during pregnancy and in different individuals at similar periods of gestation.

4 Tonus increased progressively in degree as pregnancy advanced, in those patients who exhibited a measurable amount.

5 An unusual increase in tonus appeared in primigravidas during the 8th month, but not until the 9th month in the case of multigravidas.

6 Although primigravidas experienced increases in tonus earlier and more often in pregnancy than did multigravidas, the ultimate level of their tonus did not exceed that of the multigravidas.

7 During the last lunar month of pregnancy, less than half of all patients exhibited any measurable tonus.

8 From these observations, it is concluded that knowledge of the uterine tonus present during pregnancy is of no value in predicting either the time of onset of labor or its character.

THE FUNCTIONAL ANATOMY OF LABOR AS REVEALED BY FROZEN SAGITTAL SECTIONS IN THE MACACUS RHEBUS MONKEY

D. N. DANFORTH, Ph.D. M.D., R. J. GRAHAM, B.S. M.B., and A. C. IVY, Ph.D. M.D.
Chicago, Illinois

UNTIL recently our concepts concerning the action of the human uterus were based almost wholly upon principles which were developed nearly half a century ago. These principles arose from two general sources first, clinical observation of the laboring uterus, and second, studies of frozen sagittal sections of women who had died in labor. A relatively large number of human frozen sections have been made and their study has contributed much to our knowledge. However the sections have been made under such varying circumstances, in regard to the cause of death and the type of labor as to engender skepticism concerning their true representation of the normal process. The freezing methods were slow and in some instances the specimens were not frozen until a number of days after death.

Since the evidence obtained by the frozen section technique is essential for a thorough understanding of the process of evacuation of the uterus, our work was undertaken to obtain such evidence under uniform conditions as to the cause of death and the time and method of freezing. It was believed that the possession of such evidence for the uterus of a subhuman primate would supplement and render it possible to evaluate more accurately the evidence supplied by the human specimens.

In this study rather extensive chronological evidence of the anatomicophysiological changes occurring in the laboring monkey uterus has been obtained. The *Macacus rhesus* was chosen as a suitable subject because of our familiarity with the uterus of this animal, because of its close anatomical and physiologi-

cal similarity to the human uterus, and because certain points of evidence required could never be obtained in the human being. Of course, results obtained in one species must be applied to another with reservation. However our knowledge of the gross, comparative, and functional anatomy of the rhesus uterus indicates that the processes concerned in evacuation should be fundamentally the same in both species.

ANATOMICAL CONSIDERATIONS

Before considering our own data, it is important to obtain a clear understanding of the anatomical divisions of the nonpregnant uterus and their fate in early pregnancy. These points are stressed, first, because they are essential to an adequate understanding of the subject which we wish to present, and, second, because they are not generally used despite their thorough and adequate demonstration.

Until the early part of the present century the human uterus was considered as being composed of two essential parts: cervix and corpus. The term "isthmus" had been employed upon occasion, but it was not until the work of Aschoff in 1905 that the isthmus was seen to be a definite structure, distinct from both cervix and corpus, anatomically as well as functionally. Since this time the subject has been considered by numerous authors, the overwhelming majority of whom subscribe to Aschoff's observations. The work of Stieve, in 1927, has emphasized and extended the observations of Aschoff and now serves as the classic description of cervix and isthmus uteri and their intrinsic changes in pregnancy, labor and the puerperium. In addition to these, the comprehensive article by Frankl is most valuable.

From the Department of Physiology and Pharmacology
Northwestern University Medical School.

This work was made possible by a gift in honor of Dr. I. M. Danforth.

The uterus is now considered as being composed of 3 essential parts the cervix, isthmus, and corpus. The cervix and corpus require no description in this communication.

When the uterine cavity is examined in a frontally sectioned uterus, the cavum corporis is seen to terminate inferiorly by a narrow canal, which soon widens into the spindle-shaped canal of the cervix proper. The length and structure of this canal varies in different specimens, and with parity. Ordinarily it is approximately 6 to 10 millimeters in length, and slightly narrower at its superior extremity. In many specimens the lower extremity can be distinguished grossly, but in others the canal terminates gradually in the cervical lumen. It is to the tissue which surrounds this canal, throughout the thickness of the uterus, that the term *isthmus* has been applied. The "anatomical internal os," is discernible with the naked eye. It is a definite muscular constriction which is often referred to, inadequately, simply as the "internal os." Aschoff adds that "at this point, where there is distinguishable externally a slight constriction, where as a rule there is the tight adhesion of the peritoneum, and where the first large transverse branches of the uterine artery enter the muscle substance, lies the upper limit of the isthmus." Again, to quote Aschoff, the lowermost extent of the isthmus is the so called "*histological internal os*," is the "line of demarcation between the (columnar) epithelium of the cervical canal and the corporeal epithelium, but not, as is so often said, the upper limit of the arbor vitae. The fold formation cannot be used in the determination of the line of demarcation. Furthermore, here the cervical and corporeal glands mingle." The transition from cervix to isthmus is therefore a gradual one, which occurs over the course of 1 or 2 millimeters or more. Frankl states that with experience this transition is often distinguishable grossly. Structurally, the isthmus resembles the corpus, but there are certain essential differences. The mucosa is thinner than that of the corpus, is richer in supporting tissue, and poorer in glands. The musculature is more poorly developed than that of the corpus, better so than that of the cervix.

The following changes are reported during pregnancy. Until the end of the second month the canal of the isthmus remains narrow, but it lengthens considerably, up to 2 to 3 times its former length. (It is of incidental interest that when a vaginal hysterotomy is performed at this stage of pregnancy one might, unless cognizant of these isthmic changes, attribute the greatly increased distance from external os to ovum chamber as being due solely to an increase in the length of the cervix. Stieve's investigations show quite clearly that there is no significant increase in cervical length. The increased distance from anatomical internal os to external os is due almost entirely to lengthening of the isthmus.) In the third month the wall of the isthmus unfolds quite rapidly, and the canal widens to form a part of the general uterine cavity. From this time until the conclusion of pregnancy, the boundary between the general uterine cavity and the cervical canal is the histological internal os of Aschoff, which now becomes known clinically as the *obstetric internal os* (O I O). (This differentiation is important, since it emphasizes the inadequacy of the unqualified term "internal os.") At term the isthmus uteri measures from 7 to 10 centimeters in length, thus making up between one fifth and one fourth of the total sagittal length of the uterus.

The nonpregnant monkey uterus. Three nonpregnant rhesus uteri have been studied. A section of one of these is shown in Figure 1. The major difference between the rhesus and human uterus is the cervical canal, which is straight in the latter, tortuous in the former. The tortuosity of the rhesus cervical canal is due to the presence of nipple-like projections (colliculi) from the walls of the cervix. Our findings concerning the location of these colliculi are not entirely in agreement with those reported by other workers and will be considered in detail in a later communication. Briefly, in all of the specimens studied we have observed 4 such projections, the 2 upper lips of the cervix, the 2 lowermost, the external cervical lips. Histological examination of the nonpregnant specimens indicates that the cervical canal extends from the ex-

ternal cervical lips to a point on the upper aspect of the internal lips. The isthmus appears to extend from this latter point upward for a distance of 8 to 10 millimeters. The remainder is corpus.

It is of interest that a physiological sphincter exists in the rhesus uterus at the junction of cervix and isthmus (at the site of the obstetric internal os). This can be felt to contract about the examining finger and balloon records can be made of its activity (Ivy Hartman and Koff, Danforth and Ivy).

Changes in the monkey uterus during pregnancy. No sections during early pregnancy are included in our series of animals. The work of Franke upon an allied species (*Cercopithecus cynomorphus*) however serves to fill this gap. Despite the fact that his work was done before the demonstration of the isthmus uteri Franke's careful descriptions leave little doubt of the fate of this structure during early pregnancy. According to his observations, the isthmus in this species unfolds and the canal widens in a manner which is essentially similar to that described for the human being. After the widening occurs, the junction between the uterine cavity and the cervix is at the level of the internal lips of the cervix. This latter is in agreement with our findings. Thus the internal lips definitely mark the obstetric internal os anatomically so that it may be followed throughout labor.

METHODS

Thirty three *Macacus rhesus* monkeys were studied. Three were nonpregnant controls. Three were sacrificed late in pregnancy prior to the onset of labor. Six were sacrificed at various stages from the onset of labor to complete effacement and dilatation of the cervix. Sixteen were sacrificed during the second stage of labor: 1 during the third stage, and 4 at various intervals from hour to week post partum.

The descriptions by Hartman and by Hartman and Strauss were found to be most helpful in the diagnosis of labor in the early animals of this series, and in the handling and care of all the animals.

The progress of labor was followed by abdominal palpation and digital vaginal examination. When the desired stage of labor was reached the animal was lightly anesthetized with intravenous sodium pentobarbital. This drug did not inhibit the uterine contractions perceptibly. The anesthetized animal was fastened by light cords to a rectangular metal frame which maintained a modified lithotomy posi-

tion. At the height of a uterine contraction the animal was lowered into the freezing chamber.

The freezing solution was kept ready for immediate use. The chamber consisted of an insulated, galvanized iron tank containing a mixture of 95 per cent ethyl alcohol and chipped dry ice (solid carbon dioxide). After a period of time this mixture reaches a temperature of -70 to -80 degrees C., and maintains itself there until all the dry ice has vaporized.

While freezing, the animals were kept completely submerged. They were allowed to remain in the chamber for at least one hour so that they reached the temperature of the freezing mixture.

By means of a motor driven band saw, with a movable platform, the upper abdomen, tail and lower legs were removed, and a median sagittal section of the remaining torso was made. The cervix was cleanly bisected in all instances.

While in the frozen state direct outline tracings of the sections are made and measurements taken, both the specimens themselves and the tracings being utilized. Precise pen and ink drawings were prepared by the artist from the direct tracings. Wash drawings are prepared from the specimens in order to illustrate certain points of detail which were not apparent in the pen and ink. In each of the frozen specimens, a section was made one half inch lateral to the midline. This half inch slice was placed in 1 per cent formalin, and from it histological sections of the uterus were made. These are not reported here, except in so far as they are necessary for the confirmation of results.

Of the 33 specimens available, 11 representative ones have been selected for reproduction at this time.

In regard to the measurements, it is emphasized that it is our purpose not to present a rigid statistical analysis of labor but rather to gain knowledge of the general trends in labor. The variation in measurements of this type is considerable, and the possible ways of measuring the same structure are legion. In order that variations might be reduced to a minimum, all measurements were made by the same individual utilizing precisely the same technique in all specimens. All measurements were verified at least twice. It is perhaps unnecessary to point out that rigid statistical treatment of results such as these is a meaningless procedure.

The following measurements and ratios are presented at this time:

1. The total internal sagittal circumference of the uterus.
2. The greatest length from the internal aspect of fundus to plane of external os.

OIO obstetric internal os E O external os
*Since the internal circumference is obviously irregular the extent of the accuracy of the measurements may be subject to question This problem can be tested by ascertaining whether the circumference bears a rather constant ratio to the length or long diameter of the uterus which is roughly an ellipsoid The ratios are surprisingly constant, and prove the relative accuracy of the method of measurement. Measurements in this table as in others are in centimeters

3 Relation of the cervical lips to the anatomical conjugate, to the symphysis, and to the promontory of the sacrum (In this report the term true conjugate is used synonymously with anatomical conjugate, to indicate the distance from the superior edge of the symphysis to the sacral promontory It is to be distinguished from the obstetrical conjugate which is the shortest distance from the symphysis to the promontory)

4 Sagittal circumference of the uterine cavity from obstetrical internal os anteriorly to obstetrical internal os posteriorly

5 Total length of the cervix

6 Sagittal circumference of the uterus below the insertion of the placenta, or below a retraction or constriction ring

For purposes of comparison all of the published human frozen sagittal sections were subjected to similar, though necessarily less exact, measurement These are not included in the present report, except to indicate certain points of similarity

RESULTS

In the discussion of results, the first and third stages of labor have been considered in accordance with the usual definitions, respec-

tively, from the onset of labor until complete dilatation of the cervix, and from delivery of the babe until after the birth of the placenta For purposes of description it has been found advisable to divide the second stage into 3 sub-stages, rather than to consider it as a whole as is customary Substage II A has been used to designate the changes occurring from the time of complete dilatation until separation of the lower border of the placenta occurs (v 1) Substage II B has been used to indicate the changes occurring from the time of separation of the lower border of the placenta up to, but not including, the birth of a part Substage II C includes the changes from the birth of a part to the birth of the entire fetus These sub-stages are clearly evident in our sections An example of a complete labor protocol is shown in Table I

Of the 30 specimens during labor illustrations of 10 have been selected for reproduction at this time, as representative of the changes which have been observed. These are the following

1 (Monkey 4, Series 6) Questionable early labor. Dilatation 1 cm. by vaginal examination. (Figs. 4 and 5a.)

2 (Monkey 14, Series 8) See Table I. (Figs. 3 and 5a.)

3 (Monkey 19, Series 9) In labor 1 hour and 45 minutes. Dilatation 4 cm. by vaginal examination. Forewaters protruding through external os. (Figs. 4 and 5a.)

4 (Monkey 30, Series) Duration of labor unknown. First vaginal examination revealed complete dilatation. Sacrificed immediately (Figs. 5 and 5a.)

5 (Monkey Series 6) In labor about 1 hour. Head upon the perineum. (Figs. 6 and 6a.)

6 (Monkey 10, Series 19) In labor 1 hour and 5 minutes. Bearing down with pains for about 25 minutes. Felt the vaginal introitus. (Figs. 7 and 7a.)

7 (Monkey 23, Series 20) Duration of labor unknown. Animal suddenly seen to be bearing down. After period of observation, she was sacrificed immediately after delivery of the head. (Figs. 8 and 8a.)

8 (Monkey Series 3) In labor 4 hours and 5 minutes. Sacrificed after delivery of head and thorax (Figs. 9 and 9a.)

9 (Monkey 31, Series 26) Sacrificed immediately after delivery of stillborn baby after labor of unknown duration. Placenta *in situ*. (Figs. 1 and 1a.)

10 (Monkey 3 Series 7) Precipitate labor. Sacrificed 1 hour after delivery of placenta. (Figs. 1 and 1a.)

The figures presented in Tables II to VII are averages for all specimens in the par-

ticular group indicated. All measurements were made from the sagittal surface only. It is regretted that lack of space prevents the publication of all of the measurements at this time, and that only averages of the entire stages may be presented. Trends which are apparent within the stages are thus not evident, except for those which are illustrated in the graph which is included. Certain of these trends will be mentioned, then, without presentation at this time of the evidence which substantiates them. Also, in order to conserve space, the ranges of the figures used in computation of the averages are not included in this communication. The figures are sufficiently constant that the authors ascribe definite trend significance to them.

ANALYSIS OF STUDY

The problem of precise differentiation of the fate of the various uterine segments in frozen sections of the human uterus offers difficulty because of the absence of gross fixed landmarks in this species. After dilatation of the cervix has started there is no definite means of

Fig 1. Sagittal section of adult nonpregnant rhesus uterus, (x 1). A, A', external cervical lips, B, B', internal cervical lips, C, upper boundary of isthmus uteri.

determining the upper boundary of the cervix. The bladder reflection, commonly stated as being a rather definite indication of the upper limit of the isthmus, has been found to be of no value in the instance of the human frozen sections. Similarly, this point has been most disappointing as a landmark in the monkey

surface of the uterus of monkey 21. The fetus, membranes and placenta have been removed. The two lips of the cervix are apparent as ridges crossing the uterus at its extreme lower extremity and about 2 centimeters above this, respectively. The thickened "ring" above these ridges is the physiological retraction ring. The lower edge of the anterior placenta is seen to extend precisely to this ring, which marks the junction of lower and upper uterine segments. The posterior placenta was seen to have been placed somewhat laterally, but its lowermost extremity likewise reached just to this ring. In this specimen the maximum retraction of the isthmus posteriorly is readily evident.

In the consideration of results, the exact proportions of the term uterus prior to the onset of labor have not been estimated. The 3 animals which were sacrificed prior to

labor were of smaller stature than the others of this series. In addition, the fetal proportions indicated that the animals were in late pregnancy, but not yet at term. The early first stage measurements are therefore taken as being representative of maximum term size of the uterus.

The results will be discussed under two general headings: (1) Changes in the uterus during labor, and (2) incidental pertinent observations. For the most part the results require but little discussion since the illustrations and tables are self-explanatory.

Changes in the uterus during labor. Stage I. During the first stage of labor there is only slight shortening in the total internal sagittal circumference of the uterus. The dimensions of the cervix and the position of the cervical lips with respect to the true conjugate are similarly not altered significantly—this despite

Fig. 5.

chosen the lower border of the placenta as being at the approximate lower level of the corpus uteri. In addition to this in many of the specimens the uterine wall thickens abruptly from below upward at a level coinciding with the lower border of the placenta. This finding adds credence to the arbitrary division indicated above. The authors realize fully that this is by no means a precise indication of the upper boundary of the isthmus. Because of the constancy of the findings however it appears that this is a satisfactory means of indicating the activity of this portion of the uterus in contradistinction to the ac-

tivity of the corporeal segment and cervix. In full cognizance then of the possible fallibility of the indicated upper extent of the isthmus uteri we shall refer to the *isthmus segment* of the uterus as being that portion which lies between the internal lips of the cervix below and (1) the lower border of the placenta or (2) the region of a physiological retraction ring above. By these means of division of the uterus one may follow in successive specimens the activity of the *corporeal segment*, the *isthmus segment* and the *cervix*.

This means of differentiation is well shown in Figure 3 which represents the internal

Fig. Graph showing the relative rate and extent of shortening of the total internal circumference of the uterus, of the corpus, and of the isthmic segment, during the first and second stages of labor.

the fact that dilatation is occurring.

the calculations in the tables, the 100 per cent measurement of the first stage is taken as an average of all first stage animals, whereas individual animals during the first stage showed progressive, significant isthmic shortening with no significant change in the corpus.

Stage II A During the early part of the second stage isthmic retraction progresses, and at this time becomes maximal. Progressive shortening of the corpus is now evident. There is no appreciable change in the length of the cervix during this period. The change in the level of the cervical lips with respect to the true conjugate however is marked. It is seen that during this substage the anterior lip of the cervix rises above the level of the symphysis. The posterior lip also rises significantly but not as extensively as the anterior.

Stage II B Obviously just prior to the birth of a part much descent of the fetus has occurred and this is reflected by an acceleration in the rate of corporeal retraction. Maximal shortening of the isthmic segment has already been attained and is sustained throughout this substage. The length of the cervix itself has undergone little change but the position of the lips with respect to the true conjugate shows further alteration. Anteriorly the external lip remains at a high level above the symphysis, and posteriorly the lip has reached the level of the sacral promontory.

Stage II C Examination of the specimens in this substage shows that after a part is born the uterus contains but little of the fetus, most being found in the vagina and that after half of the body of the fetus is born the uterus contains only placenta and amniotic fluid. Hence, much shortening of the entire longitudinal circumference should and does occur. It is of

Interest that throughout the only evidence of longi-

tudinal shortening of the

nior lip averaging almost 2 centimeters above the symphysis, the posterior being located at about the level of the sacral promontory. The extent to which the cervical lips rise in the monkey is greater than that revealed by the frozen sections in the human being and also greater than that seen in the experience of obstetricians. Since the upward excursion of the cervical lips is limited by the fascial supports of the cervix (which include the pubocervical fascia and the transverse cervical and sacrouterine ligaments), it is apparent that in the monkey these supports are more flexible than in the human being. Caldwell and Stillman of the Sloane Hospital for Women have made preliminary studies which clarify this subject in the parturient woman. Metal clips have been placed upon the cervix and x-ray pictures made during the various stages of labor. Their studies indicate that the cervical lips pull up considerably higher than is generally believed, but not as high as in the monkey.

Stage III During the third stage there is continued shortening of the corporeal and isthmic segments. Cervical length, again, is not significantly altered. The almost instant return of the uterus to its general contour prior to the beginning of pregnancy is well illustrated by specimen No. 10, sacrificed one hour postpartum.

It has doubtless been observed that in this discussion of uterine changes during labor no mention has been made of the "thinning" which is believed to occur normally in the lower pole of the uterus. Our findings show that *longitudinal* thinning or actual stretching, does not occur normally in the isthmic segment in the monkey, with the single exception of the late second stage when the lower pole of the uterus relaxes to receive the placenta. All the evidence indicates that the region of the isthmus is not only the first portion of the uterus to undergo shortening in labor, but that, in addition, this shortening is progressive, and sustained until the late second stage. At cesarean section in the human being the illusion of thinning may possibly be produced by the contrast of the more marked and evident corporeal retraction, to the lesser but maximal retraction of the isth-

Fig. 13

mus. Anesthesia may also be a factor. Actual longitudinal thinning of the isthmus may occur under certain circumstances in the human uterus, but we find no evidence of this in the monkey, nor have we found definite evidence of it in the human frozen sections in the absence of disproportion. In the instance of neglected disproportion the cervix is held fast by the taut cervical supports. Contractions of the powerful corpus uteri of necessity lead to longitudinal stretching with injury and ultimate rupture of the weaker lower pole of the uterus. The rupture of old cesarean section scars, often cited as evidence of isthmic thinning, occurs perhaps as frequently prior to, as during, labor. It is doubtless due to mecytasis or lengthening of the *circular* muscle, which occurs as the isthmus adapts itself to its contents during the second half of pregnancy, or as it enlarges laterally during early labor to allow the passage of the fetus.

Incidental observations The examination of the specimens brings to light many factors incidental to labor which heretofore have not been fully appreciated. Among these are

Uterine retraction of the corporeal musculature As may be observed in the illustrations retraction is quite even throughout the corpus in the first and third stages, and fairly so in the early second stage. In the late second stage however retraction is grossly unequal in the various parts of this structure. Certain of the human frozen sections, notably many of those of Canton and Gonzalez, show similar inequality of corporeal thickness at this time.

Excursion with ultimate complete obliteration of the vaginal vaults As the cervical lips rise in the pelvis, so must the vaginal fornices rise. This accordion-like action of the vagina is perhaps not fully appreciated. Its tremendous distensibility is well illustrated in Figures 9 and 9a.

Evidence of beginning separation of the placenta before completion of the second stage If a monkey is unrestrained in the third stage of labor she will pull upon the umbilical cord immediately after the birth of the fetus, to remove the placenta. If it does not come away after the first pull, it generally does so after a few minutes. This indicates that in the monkey the placenta is almost completely separated at the end of the second stage of labor. This is verified by our sections. Early separation of the placenta has often been postulated in the human being but there is no definite evidence either supporting or refuting it. In favor of such a postulation is the recent confirmation by Steer and Sullivan in a large series of cases that the placenta may be delivered almost invariably within 2 to 3 minutes after the baby if a Credé maneuver is performed at the moment when the uterus first adapts itself to its suddenly diminished contents. This observation has been made by numerous other workers since its original presentation by Chantreuil in 1870, following the suggestion of Credé.

SUMMARY AND CONCLUSIONS

1. The present understanding of the anatomy of the nonpregnant and early-pregnant uterus has been outlined. The necessity of considering the isthmus uteri as an important and distinct part of the uterus has been emphasized. The terminology used and is based on anatomical principles and

on comparative anatomical and physiological observations.

2. Frozen sagittal sections of 30 *Macacus rhesus* monkeys at consecutive chronological phases of late pregnancy labor and the puerperium have been made. Reproductions of 10 of these and of 1 of 3 nonpregnant animals are here presented. The entire series has been thoroughly studied with the view to determining the precise changes which occur in the laboring primate uterus. The conclusions recorded are based upon the analysis of the entire series of animals. All of the available human frozen sections have been similarly analyzed. The latter are not presented at this time. Although the human specimens were not satisfactory for the observation of many of the details, one receives the definite impression that the findings in the monkey are for the most part characteristic of those occurring in the human being with only a few minor quantitative differences. Our observations concerning the changes in the human uterus are generally in agreement with the models prepared by Dickinson and Belkue which are based upon a similar analysis of the human frozen sections.

3. In the *first stage of labor* retraction is limited chiefly to the isthmus uteri in the monkey. The intrinsic dimensions of the cervix do not alter appreciably despite the facts that dilatation occurs and that the lips rise to a slightly higher level in the pelvis. The total internal circumference of the uterus and the internal circumference of the corpus show only a slight amount of reduction in the first stage.

4. In the *second stage of labor* in the monkey the cervix rather quickly retracts to or above the true conjugate. Obviously this elongates the vaginal portion of the birth canal. On the basis of the total internal circumference retraction in the corpus and isthmus is at a proportionally similar rate during the early portion of the second stage. Maximal isthmic shortening occurs early however and is sustained until this segment relaxes to receive the placenta. The corpus, on the contrary

as to manifest progressive shortening as it becomes especially a part is born

5 The cervical lips ascend to a higher level in the monkey than in the human being

6 The question of "thinning out of the lower uterine segment" is discussed briefly. Longitudinal lengthening of the isthmic segment does not occur in the monkey, and human frozen sagittal sections do not support its occurrence in this species in the absence of disproportion. The isthmic segment does seem relatively thin in contrast to the corpus which lies above. The latter is more bulky to begin with, and it is possible that this may lead to the clinical impression of a "thinned out lower uterine segment," whereas, in reality, the isthmus is undergoing perceptible longitudinal shortening. Our material allows no conclusions concerning the activity of the circular muscle of the isthmus during labor. Obviously, however, definite circular lengthening of the lower pole of the uterus must occur in order that the fetus be allowed to pass. Circular lengthening, then, may account for thinning in the lower portion of the isthmic segment. However, this does not explain thinning as it is commonly thought to occur throughout this segment.

7 In the monkey, and likely in the human being, separation of the placenta is almost complete by the end of the second stage of labor. In our specimens the lower edges of the placenta were separated by the time a part was born, after which separation of the remainder of the placenta progressed rapidly.

8 At the beginning of the *third stage of labor* the uterus shortens and retracts still

further. The placenta then lies partially in the vagina, partially in the lower pole of the uterus. After removal of the placenta there is almost instant return of the uterus to its general shape prior to pregnancy.

9 Some incidental observations are recorded.

The authors wish to express their appreciation to Miss Charlotte Holt for her interest in the preparation of the illustrations which accompany this presentation.

RECURRENT FRACTURE

WILLIAM A. EVANS, J. M.D. Detroit, Michigan

IT is commonly believed that when a fracture heals without deformity the bone structure at the fracture site is as firm if not more so than before. This certainly seems to be true in most instances. Fractures which recur at the site of a fracture deformity or of an old pathological process where there is structural weakness are easily understood and do not call for comment. Such recurrent fractures were apparently frequent in the time before Roentgen and Lister when wound infection and the inaccurate reduction of fracture deformities were more common. There is, however, a group of cases deserving consideration in which the cause of refracture is not as apparent.

Small groups of these cases have received comment in the European literature. Troell, in 1917 reported 4 cases and mentioned a few others. He pointed out that the new fracture is never an anatomical copy of the old one even when the latter is not completely healed. Disease atrophy and foreign bodies at the fracture site were thought to predispose to refracture. His cases included (1) a 50 year old man with a fracture of the humeral shaft showing complete healing after operative reduction and then refracture 5 months later (2) fractures of the mid radius and ulna in a 12 year old patient reduced by open operation and ivory implants, and a refracture 7 months later (3) 2 fractures of the femoral neck occurring 6 years apart in a 65 year old male and (4) 3 fractures of the tibia the third one occurring 13 years after the other two in a 31 year old male.

Peritz, in 1927 reported 6 cases in children between 9 and 16 years of age of whom were siblings. The children were otherwise healthy and there had been no other fractures. The interval between the fractures was from 3 weeks to 33½ months. As a possible explanation she gave deficient callus production at the first fracture site due to the very limited injury to the periosteum. Two of the fractures were subperiosteal in type and there was formation of calcium-poor zones, such as are seen in hunger osteopathy and the so called "chronic" fracture. Other factors considered were late results of starvation during the war and an avitaminous of the winter months.

From the Department of Roentgenology Children's Hospital of Michigan

Inasmuch as the cases appeared at that season of the year. It was further noted that all fractures had occurred in the mid-diaphysis and it was believed that an injury to the nutrient artery and the resultant changes in the bone might be a basis for refracture.

Strauss and Mandel, in 1932 reported 7 patients with fractures recurring after intervals of 4, 7, 3, 16, 28, 32 and 36 weeks. The patients were between 6 and 27 years of age—3—14, 17 and 6 years of age—had fractures in the forearm, 3 in the lower leg, and 1 in the thigh. Although the fractures recurred at the exact sites of the old fractures, they pointed out the slightly different character and configuration of the fracture lines. They regarded refractures of this type as very rare and considered malnutrition as a factor in their causation.

Slavero, in 1939, has reported 16 cases of refracture but most of these occurred in cases in which there was much deformity at the first fracture site or in which the first fracture had been complicated by infection. In 6 instances, however the basis for refracture was not so readily apparent. These patients were 13, 12, 11, 16, 13, and 32 years of age and the fractures had recurred after intervals of 8, 11, 6, 5, 21 and 22 weeks, respectively.

The x ray was used very sparingly and, in some of the cases, it would appear that the healing of the fracture had not been complete. The author gives the general causes of defective healing which are well known but has regarded fractures of the forearm in children as a special instance. Here the fractures may be subperiosteal with insufficient injury to the periosteum to cause callus formation or there may be injury to nerve or nutrient artery as possible basis for the refracture.

MATERIAL

In a study of refracture, one may first consider a group of cases in which there is some demonstrable and reasonable basis for the second fracture. We have encountered instances of generalized and local pathological conditions of bone which predisposed to refracture and one instance in which a fracture had recurred many years after the implantation of a foreign body in the successful repair of the first fracture.

Multiple fractures are a well recognized feature of osteogenesis imperfecta, but perhaps less well recognized is the tendency for the fractures to recur at the same site in different bones. This is well illustrated in Case 1 in which there were multiple fractures of both femora and of the right tibia, the recurrent fractures appearing at, or near, the old fracture sites. This is in part due to the deformity with which healing occurred, resulting in a structural weakness which predisposed to a refracture at that point. In other instances, however, it would appear that the healing of the fracture had occurred with the formation of particularly fragile bone in that area and this seems to be borne out by the character of the recurrent fracture line.

Recurrent fractures in an area of pathological bone structure and at the site of a foreign body are readily understood and are well illustrated by Cases 2 and 3. Nevertheless, it is of interest to observe that although the healing of the first fracture in Case 2 was apparently quite normal, in reality an osteitis fibrosa had developed and was not discovered until the time of the second fracture. In Case 3 there was without doubt a fragility of the bone structure about the bone screw implants, but this was not evident from an examination of bone structure by x-ray either at the new fracture site or of the intact bone about the proximal screw. Not only had there been no absorption of bone about the screws, but the bone was unusually dense.

The largest group of cases in this series is made up of those having recurrent fractures of the bones of the forearm. Others have commented on the peculiar liability of fractures involving the shafts of the radius and ulna in children to recur, and this is borne out by the fact that we have encountered 8 such cases although this is not one of the most common sites of fracture either in children or adults. The most common fracture in children is at the lower end of the radial diaphysis, 1 to 2 centimeters proximal to the distal epiphyseal line. No instances of a refracture in this area were encountered, and it may be inferred that here healing takes place with the formation of a bone structure more solid than before. This idea receives some support from Cases 16 and 17, in which a Colles' type of fracture was followed after a short interval, in 1 instance only 3 months, by a second injury with fracture in the forearm. Although the type of injury seemed to be due to the same mechanical forces, the second fracture did not occur at the old fracture site which would have been the case if that were a *locus minoris resistentiae*, but rather in the shaft

some distance proximal to the old fracture site.

The 8 cases with recurrent fractures in the mid-portion of the shafts of the radius and ulna give evidence that in children, at least, healing of fractures in this area may fail to restore the bone to its original strength. The altered character of the bone structure after healing is shown by the peculiar configuration of the second fracture lines which was observed in all instances and suggests an abnormal fragility of the bone. These second fracture lines resemble the fracture lines seen in osteogenesis imperfecta, as well as the fracture lines observed in rickets and the "insufficiency fracture" described by Hansson and others.

One reason that has been suggested for the increased fragility in these cases is an involvement of the nutrient foramen and a consequent impairment of the blood supply to the bone. This is conceivable in Cases 4, 6, 10, and 11, but would not apply to Cases 5, 7, 8, and 9, in which the fractures have occurred at some distance from the positions usually given for the nutrient foramen. Nevertheless, it is possible that in the shaft where the cortex and medulla are sharply differentiated, the blood vessels or nerves may be more seriously injured than in the cancellous portions without actual involvement of the foramen.

Other possibilities for the fragility of the bone are the complications present during healing in some of the cases: a pressure ulcer in the skin of Case 4, a respiratory infection and incomplete immobilization of the arm in Case 7, chickenpox in Case 9, and soft tissue atrophy in Case 10.

A further possibility is a constitutional peculiarity of these children. Many of them tended to be undernourished, and the extremities were strikingly thin and wiry. Six of the 8 were definitely below the average weight for their age and height and were described as "poor eaters" and "delicate," as compared with their brothers and sisters. A mild form of osteogenesis imperfecta is suggested by the thin bluish sclerae and the hyperflexibility of the ligaments which many showed.

In the treatment of fractures of the forearm in children, where the shafts of the radius and ulna are involved, it seems advisable to recommend that these children, and those responsible for their care, guard against the possibility of further injury even after recovery seems complete. The liability to refracture might also be lessened if the food intake could be increased and the nutritional state improved.

Comparable in many respects to the 8 cases of refracture in the radius and ulna are the 2 cases (12 and 13) of refracture in the clavicle. The

Fig. Case Severe osteogenesis imperfecta with numerous fractures of the bones of both legs. Fractures occurred in the left femur in April, 1938, April, 1939, April, 1939 and August, 1940. All of these fractures took place at the same site in the femoral shaft after osseous union had occurred.

shafts were involved where the cortex and medulla are sharply differentiated and near the nutrient foramen. Both children suffered upper respiratory infections during the period of healing and the character of the second fracture lines indicated an abnormal fragility of the bone. Some features of osteogenesis imperfecta were observed in Case 2 and this patient was below the average weight for his height and age.

Two cases remain which present certain new features and raise new questions. Case 14 is not strictly pertinent to this study for although the 2 fracture sites in the tibia appear identical, the growth of the bone during the interval of 6 years has displaced the old fracture site some distance distal to the new fracture site. Thus we are not faced with a true exception to the observation that refractures occur in the compact structure of the shaft rather than in the spongy areas at the ends of the long bones. Case 5 concerns a very obese boy of 18 who sustained 3 fractures in the same area of the fifth metatarsal bone with intervals of 5½ months and 4½ months between them. The fractures were each

preceded by a definite acute trauma producing severe pain and each injury was sustained in a slightly different way under different circumstances. March fractures usually involve the second metatarsal bone although Koch has described one in the fifth metatarsal in a deformed foot. Furthermore Watson Jones states that metatarsal fractures due to muscle strain may recur. Although the obesity in this instance may have been productive of muscle and bone strain, an invidious history of progressive pain without acute injury which is characteristic of march foot is quite unlike the history in this case. The rather short interval between the fractures suggests that healing may not have been complete at the time of the refracture. This is contradicted, however by the facts that the patient made a complete clinical recovery after each fracture using his foot in a normal manner again without pain and that the new fracture lines were of slightly different configuration than the old ones.

FURTHER FACTS ON RECURRENT FRACTURES

Upon the observation of a recurrent fracture, the question arises as to whether the healing of the first was complete. In some of the cases the x-ray studies indicated complete healing and in all cases there was clinical evidence of healing

A study of the chart in a monograph of the Society for Research in Child Development (14) giving the growth in length of the tibia each during childhood indicates an average growth of 1 centimeter in the interval between the fractures. Assuming a growth of 1 centimeter at each end would leave the new fracture well proximal to the old fracture site. Inasmuch as the child was very close to the average weight and height and the growth of the tibia almost equal at each end, the assumption seems valid.

April 10, 1938 August 20, 1938 November 29, 1938 September 14, 1939

Fig. 2. Case 1. Similar changes are seen in the right thigh where fractures of the femur are known to have occurred in June, 1937, April, 1938, August, 1938, and (?) September, 1939.

as indicated by normal use of the part without pain. The interval between the fractures, although in some instances barely over 3 months, exceeded the period generally considered necessary for healing in uncomplicated cases. However, the available clinical evidence of complete healing of human fractures is admittedly not entirely adequate and for further information one must turn to animal experimentation. Lindsay and Howes, in 1931, reported studies on the breaking strength of healing fractures in the fibulas of rats. They quote Leriche to the effect that the healing rate in bone was the same for all animals that he studied so that their results may have an applicability to man. They found the breaking point of the rat fibula to be at a strain of from 285 to 580 grams. During healing, strength first appeared at the fracture site on the sixth day and there was a rise in strength to an average resistance of 341 grams at 21 days. This was followed by a slight fall to 277 grams on the thirty-third day and a subsequent rise to 465 grams at 45 days. At this time the bone at the fracture site was as firm as elsewhere and there was no predilection for the fracture to occur at the old fracture site. The first peak of healing strength coincided with the maximum extent and density of the callus and the subsequent fall was correlated with the absorption of the callus surrounding the bone and in the medullary canal. Further observations (6-9) with the rats on various diets showed most consistently that changes in the quantity of food consumed and the rats

weight exert a strong influence on both the healing and the normal breaking strength of the fibulae. The greatest loss of strength was noted on a high carbohydrate diet with lesser changes on a high fat low calcium diet. Maximum healing strength was obtained in about 45 days on all diets.

November 9, 1938 Sep. 14, 1939 Dec. 14, 1939

December 7, 1935. March 23, 1936. July 9, 1936

Fig. 4. Case 2. T recurrent fractures in the shaft of the right tibia in French-Canadian boy who sustained the original fracture on November 5, 1933, at the age of 3 years and 7 months. The original films are not available but the report indicates no abnormality in the bone structure at the fracture site at that time. The healing was apparently satisfactory although cystic formation was discovered at the time of the second fracture on December 7, 1935. A third fracture occurred on July 9, 1936, and this was followed by surgical exploration with diagnosis of osteitis fibrosa cystica on the material removed for pathological study.

Haebler and Reles, in 1936 made studies on the tension and bending strength of excised canine long bones. No relation could be established between the flexibility to bending or tension and the age, weight, length, or in the calcium or water content of the bone. This is admittedly in contrast to man in whom the fragility of bones in the aged and the flexibility of the bones in the child are well recognized. Marked differences were found in different bones of the same animal. In studies on healing fractures they found that the extent and density of the callus as demonstrated by x ray may be misleading in estimating the strength at the fracture site and there was no close correlation between the calcium content of the dried material at the fracture site and the firmness of healing. Water content seemed to be of considerable importance. They believed the best evidence of healing to be painlessness under strain.

The effect of the diet and vitamin intake on the healing of fractures has been subject to much

August 23, 1934. September 3, 1934. August 1, 1936

Fig. 5. Case 3. Recurrent fracture of the femoral shaft in an 8 year old boy 5 years after the original fracture which was treated by open operation and the implantation of two bone screws.

study. A review of this material was published in a monograph by Hertz, in 1936. Recurrent fractures during attacks of scurvy were reported in sailors by Richard Walter in 1740, Mead in 1763, Marriquet in 1783, Bell in 1788, Callisen in 1798, Hammick in 1830, Budd in 1840, and Moore in 1859. Israel and Fraenkel studied this phenomenon experimentally and found that scurvy may soften a callus already formed and facilitate refracture. Their findings were supported by the experiments of Schlowasser and contradicted by those of Roegholt. Hertz made experiments on scorbutic guinea pigs and could not substantiate the conclusions of Israel and Fraenkel. Thirteen animals with fractures of the fibula were placed on a scorbutic diet after 23 days, and they died in from 54 to 77 days. All of the fractures were found well healed. Hunger osteopathy and the occurrence of a chronic fracture as the result of mechanical strain are offered as an explanation for the observations in scorbutic sailors and in the animals studied by Israel and Fraenkel. Delayed healing of fractures in subjects deficient in vitamins A, B, and D has been reported. In the cases of recurrent fracture which we have studied there was no evidence of vitamin deficiency either in the history of food intake or in the appearance of the bone structure. However, an impressive number of the patients were underweight and had poor appetite so that possibility of some food deficiency and dietary osteopathy must be considered.

A number of papers have appeared, chiefly in the foreign literature on the occurrence of in-

sidious or chronic fracture. The best examples are the march foot and the fissure fracture of the tibia which are prone to occur in young military recruits subjected to unaccustomed strain. Cases have been described and discussed by Koch, Olsson, Reischauer, Hansson, Pfahler, and others. It is generally agreed that there is no acute trauma, but that under the influence of prolonged strain a periosteal proliferation occurs followed by the appearance of a fissure in the cortex. The symptoms are insidious in onset and progressive in character. The first x-ray studies may be negative as the callus does not become demonstrable for 8 weeks or more (Koch). Fractures of this type also are seen in undernourished individuals as a manifestation of a hunger osteopathy or rickets. Although the fracture lines bear a certain resemblance to the refractures seen in this study, an identity cannot be established, for in all of our cases the refracture was accompanied by a very definite history of acute trauma, and there was no deformity or habit of behavior productive of a chronic strain. Furthermore, the old fractures were symptomless at the time of the refracture.

CONCLUSIONS

1. Fractures are prone to recur when a general or local disease of the bone is present, when healing has occurred with deformity, and at the site of a foreign body. The basis for such fractures is readily understandable.

2. A fracture may also recur at an old fracture site after healing has apparently been complete and in the absence of a significant deformity or recognizable complicating pathological process.

3. The character of the new fracture indicates an abnormal fragility of bone at old fracture site.

4. Recurrent fractures of this type are most often seen in the shafts of the radius and ulna of children. Such children are apt to have poor appetites and to be of less than average weight with thin extremities. The flexible ligaments and blue sclerae which many of them show suggest a constitutional background in common with osteogenesis imperfecta.

5. It seems desirable for children who have had fractures of the shafts of the radius and ulna to take particular care against a second injury even after the healing of the first injury appears complete and to increase their food intake for the improvement of their nutritional state.

CASE REPORTS

CASE 1. M. S., C. H. D. 3140. A white female of English nationality born on March 15, 1932, was first seen at the

Fig. 6. Case 4. Recurrent fractures of the left radius and ulna in a 9 year old boy after interval of 1 year and 1 month. First view shows appearance of healing at fracture sites 6 weeks after the first injury. Healing was complicated by a pressure sore but recovery was eventually complete. Second view showing new fractures of different character at the old fracture sites.

Children's Hospital in April, 1938, having recently sustained a spontaneous fracture of the left femur. The dates of previous and subsequent fractures are as follows: the left femur in April, 1933, April, 1938, April, 1939, and August, 1940; the right femur in June, 1937, April, 1938, August, 1938 and (?) September, 1939; the right tibia in November, 1938, September, 1939, and December, 1939.

On May 28, 1938, the neck was explored surgically and a parathyroid gland somewhat larger than usual, encountered at the right lower pole of the thyroid gland, was removed. Microscopic study of the specimen revealed nothing remarkable and the operation had no demonstrable effect on the patient's course. Theelin was given for a period without effect. An x-ray study of the spine in September, 1939 showed a low mineral content of the bone structure and the vertebral bodies had a marked biconcave configuration as the result of expansion of the intervertebral discs. Multiple fractures of the ribs were also noted. The fractures of the left femur are illustrated in Figure 1 and show the tendency to recurrence in the areas of abnormal bone structure at the old fracture sites. The condition has been regarded as an osteogenesis imperfecta and except for the deformities incident to that, the physical examinations have not been remarkable.

CASE 2. R. P., C. H. D. 92720. This boy born of French Canadian parentage on April 25, 1930, was first seen at the Children's Hospital in 1932 for bronchoscopic removal of a peanut. He was next seen on December 7, 1938, giving a history of falling while chasing another boy and injuring his right leg. It was later learned that a fracture had

Fig. 7. Case 5. Recurrent fractures of the right radius and ulna in a 7 year old boy after an interval of 5 months. The first two views show the first fractures with the appearance of satisfactory healing after 4 months. The second fractures are at the old fracture sites but are of different character.

occurred in the right tibia 5 years previously followed by satisfactory healing. X-ray studies here in 1938 (Fig. 4) showed an oblique fracture through an area of cystic disease in the middle third of the tibial shaft. There was no deformity as result of the fracture and cast as applied for 7 weeks. Healing occurred and the normal use of the part as regulated although the area of pathologic bone structure persisted.

On July 9, 1939, he fell again, sustaining another fracture in the right tibia with fracture lines similar but not identical to those observed previously. Healing was again occurring but it was decided to curette the cystic area and fill the cavity with bone chips. This was carried out on October 4, 1939, and pathological study of the material removed showed the characteristic appearance of osteitis fibrosa cystica. Satisfactory healing occurred with an uneventful recovery and subsequent roentgen-ray studies on October 31, 1939, December 26, 1939, March 2, 1940, and May 4, 1940, and November 2, 1940, revealed increasing solidity of the bone structure with no new areas of cyst formation.

CASE 3. J. S. C. H. 746 This patient, of French-Syrian parentage, born on July 6, 1931, was struck by truck which passed over his left leg on August 7, 1934. A comminuted fracture of the lower tibia was recognized and treated accordingly. On August 26, 1934, deformity of the left thigh was noted and long oblique fracture of the femoral shaft was discovered (Fig. 5). The fragments are

overriding about 3.5 centimeters, and there was callus at the fracture site, giving an appearance compatible with the date of the first injury. Because of the deformity as seen reduction was performed with removal of the callus, resection of the sclerotic ends of the fragments, traction, and correction of the overriding. With the fragments in close end-to-end approximation two bone screws were inserted. A plaster cast was applied for 8 weeks, at the end of which time good union was reported.

There was no disability or complaint until August 20, 1939, when he jumped about 1 foot from the roof of a garage and experienced pain and tenderness in the left leg. X-ray studies showed that there had been complete healing at the old fracture site in the femur. With no demonstrable osseous change about the bone screws. However, a new fracture had occurred involving the site of the more distal screw with somewhat different configuration and character of the fracture line. After unsuccessful attempts at manipulation, an operation was performed on August 26, 1939, and the lower screw which lay between the fragments, was removed. The upper screw was firmly in place and could not be moved. Traction and plaster bands were applied with the fragments in close end-to-end approximation. Healing occurred rather slowly and on April 2, 1940, he was allowed up on crutches with caliper brace. On October 6, 1940, the brace was removed and there was no pain or disability in walking except for a slight limp.

At an interview on November 2, 1940, the patient was observed to be an active child nourished, and well developed boy weighing 33.5 kilograms for height of 57 centimeters.

The X-ray report from another hospital dated November 21, 1939, describes an oblique fracture of the middle third of the right tibia. The fracture was made of very cystic bone tissue.

meters. There had been no other fractures than those here described, and in a family of 5 other siblings only one fracture had occurred and that was sustained in an auto accident. The diet had been adequate and well balanced. The sclerae appeared bluish but there was no deafness or abnormal flexibility of the ligaments.

CASE 4 S A, C H C 2530. This Armenian boy, born on March 2, 1931, fell while climbing the back of a chair and injured his right arm in April, 1937. The x-ray studies revealed greenstick fractures of the midradius and ulna. Following manipulation and immobilization satisfactory healing occurred without deformity or disability.

On July 22, 1939, in a fight over a toy wagon, he was attacked by another boy and the two fell to the ground on his outstretched left arm. X-ray studies made in Providence, Rhode Island, showed fractures of the middle thirds of the left radius and ulna with lateral and anterior angulation at the fracture sites. The deformities were reduced, and a fixation dressing was applied. On August 7 a large pressure sore was discovered and a new dressing was applied. On his return to Detroit, x-ray studies were made at the Children's Hospital on September 5, 1939 (Fig 6), and the fracture sites are well shown with bony union occurring in a satisfactory manner. The child recovered the use of his arm completely.

Enlarged tonsils were removed on April 22, 1940, and at that time the physical examination was otherwise negative.

In August, 1940, while boxing he was tripped by his opponent and fell backward on his extended left wrist. X-ray studies on August 12, 1940 (Fig 6), showed new fractures in the middle thirds of the left radius and ulna. It was evident that complete healing had occurred at the old fracture sites and the new fractures, although occurring in the same area, had a slightly different configuration of the fracture lines. Following manipulation, healing again took place.

The boy appeared quite thin and very active, weighing about 24 kilograms with a height of 131 centimeters. This is a constitutional type shown by his parents and a sister. He was described as a "poor eater" but with no peculiarities of taste and with a good vitamin intake. No fractures other than those described have been sustained by him or his family. The sclerae were rather thin but not definitely blue. There was no deafness. The ligaments about the joints were quite flexible but not abnormally so.

CASE 5 W S, C H 118080. A male child, born January 15, 1933, of German extraction, was first seen at the Children's Hospital in November, 1936, when a tonsillectomy was performed for large tonsils. The physical examination was otherwise negative. On November 26, 1939, he was pushed from a porch by his brother and sustained fractures of the right radius and ulna (Fig 7). The deformity was reduced by manipulation, and immobilization in plaster was carried out for 10 weeks. Frequent x-ray examinations revealed satisfactory progress in healing, and on March 26, 1940, healing was thought to be complete. The clinical findings confirmed this, and the boy made free use of his arm without complaint.

On April 28, 1940, 5 months after the previous injury and 2½ months after free use of the arm was allowed, he sustained a new injury to the right forearm in a fall while jumping during a game. The x-ray examinations revealed new fractures of the radius and ulna at the old fracture sites. There was, however, a slightly different configuration of the fracture lines. Immobilization in plaster for 7 weeks resulted in satisfactory healing at both fracture sites.

At an interview on October 16, 1940, the x-ray examination showed complete healing with minimal de-

February 23, 1940 March 11, 1940 June 27, 1940

Fig 8 Case 6. Recurrent fractures of the right radius and ulna in a poorly nourished, 7 year old girl, after an interval of 4 months and 2 weeks. Healing of the first fractures seemed satisfactory clinically and by x-ray on March 11, 1940, 2½ weeks after the injury. The second fractures are distinctly different in character and delineation although occurring at the old fracture sites.

formity, and there was free use of the arm without discomfort. He appeared to be a rather thin and very active boy, weighing 27 kilograms with a height of 129 centimeters. He had suffered no fractures other than those described but gave evidence of many minor cuts and bruises. There was no deafness but the sclerae were slightly bluish and the ligaments were of somewhat more than average flexibility.

CASE 6 L D, C H 105617. A girl of Irish parentage, born on December 12, 1932, was first seen in the Out Patient Department in 1934, with eczema. She complained of a prolonged cold with cough in 1939 and much enlarged tonsils were found. The tuberculin skin test was negative.

On February 16, 1940, her right arm was pulled violently while playing with an older girl, and an x-ray examination 1 week later revealed transverse fractures of the middle thirds of the radius and ulna, the only deformity being a slight anterior angulation at the fracture sites. Immobilization in plaster was carried out for 6 weeks, and there was the usual progress in healing observed clinically and by x-ray. At the end of 6 weeks she was allowed free use of the arm and, although writing with the right hand, she continued to use the left for eating and striking other children.

The second injury occurred on June 27, 1940, in a fall from a bicycle, and new fractures of the right radius and ulna were observed at the old fracture sites with, however, a slightly different character and configuration of the fracture lines. Following manipulation the right extremity was placed in immobilization in plaster for 9 weeks and there was again satisfactory progress in healing of the bone at the fracture sites.

November 9, 1935. February 24, 1936. January 9, 1939.

Fig. 9. Case 7. Left forearm of male child, no sustained fractures of the radius and ulna on 4 occasions—November 9, 1935; December 29, 1935; January 9, 1939, and August 24, 1939. On the first occasion healing as

March 9, 1939. August 24, 1939. October 7, 1939.

complicated by an upper respiratory infection and incomplete immobilization. There is good functional recovery and no deformity following the second, third, and fourth injuries.

September 4, 1937. November 4, 1939. December 2, 1940. December 28, 1940.

Fig. 10. Case 8. Recurrent fracture of the left radius in poorly nourished 3-year old girl after an interval of 3 years and 3 months. At the first injury both the radius and ulna are involved and healing is observed to be complete 3 years later on November 4, 1939. The second fracture of the radius occurring at the injury of November 2, 1940, is inconspicuous in the study of December 2, 1940, but is confirmed by the appearance of callus on December 28, 1940.

The patient was interviewed on October 6, 1940. There is free use of the arm without deformity or disability and the x-ray examination revealed complete healing at the fracture sites. She is observed to be an unusually small

and thin, but very active girl, weighing 8.5 kilograms with height of 80 centimeters. This was constitutional trait shared by the mother and her other children. She had suffered no fractures other than those described and only

Fig 11 Case 9 Recurrent fractures of the right radius and ulna in a 7 year old girl after an interval of 3 months and 1 week. Healing of the first fracture was complicated by chicken pox but appeared complete with no deformity or disability. The second fractures, although at the old fracture sites, have a different course and character.

one other fracture in the family was recalled. She had been examined recently in the medical clinic, but no cause for her low weight was discovered. Her mother described her as a poor eater but there were no fancies or peculiarities of the diet. There was no deafness but the sclerae were thin and slightly bluish and there was more than usual flexibility at the joints.

CASE 7 M S, C H E 286 This boy, born of Irish parentage on December 14, 1933, was seen at another hospital on November 11, 1935, the day following a fall out of bed and an injury to his left arm. The x ray studies (Fig 9) disclosed fractures of the midradial and ulnar shafts. Further study after the application of a plaster dressing showed an excellent end to end approximation of the fragments and a good alignment except for slight posterior angulation at the radial fracture site. The records do not reveal the length of the period of immobilization, but there is a note that on December 7, 1935, the cast was cut and passive motion applied. Convalescence was prolonged and complicated by an upper respiratory tract infection without elevation of temperature and with a negative x-ray study of the chest on December 10, 1935, and he was not discharged from the hospital until December 22, 1935.

Six days later he fell while playing and again injured the left arm. X ray films showed new fracture lines at the old fracture sites and a rather marked degree of posterior angulation. Following manipulation and immobilization an excellent position and alignment of the fragments was observed at the roentgen studies of December 29, 1935, January 25, 1936, and February 24, 1936.

Recovery was apparently complete and he had normal use of his arm until January 10, 1939, when he was pushed from a bed while playing with his sister and sustained a new injury to the left arm. Fractures were again seen in the radius and ulna at the old fracture sites. The disalignment was corrected and immobilization in plaster was maintained for 10 weeks. Good use of the arm was re-

June 27, 1940 August 22, 1940 February 9, 1941

Fig 12 Case 10 Recurrent fractures of the left radius and ulna in a 14 year old girl after an interval of 7 months and 2 weeks. Healing of the first fractures was complicated by considerable atrophy, but there was no other deformity and good function was obtained. The second fracture lines are of distinctly different character than the first, although occurring at the same sites.

gained and the clinical impression on April 18, 1939, was that the fracture was completely healed. On June 12, 1939, his foot became caught in a bicycle. Pain persisted and an x ray examination on June 15, 1939, revealed a greenstick fracture at the lower end of the tibia. Immobilization in plaster was carried out for 6 weeks and satisfactory healing occurred.

On August 24, 1939, he sustained a fourth injury to his left arm when pushed by some boys at play and for the fourth time a fracture was demonstrated in the midradius. The ulna appeared intact at this time. Satisfactory healing occurred with immobilization in plaster for 9 weeks.

At an interview on October 16, 1940, the boy was observed to be very active physically and mentally. He weighed 22.5 kilograms with a height of 117 centimeters and appeared well nourished. His mother had observed that in the past his wrists had appeared thin compared with those of his brothers and sisters and he had inclined to be "delicate" although he had recently become more robust. His diet seemed satisfactory and he had a good appetite, but he had small, poorly developed teeth. The sclerae appeared bluish and the ligaments were quite flexible at the joints but there was no deafness. He had sustained no fractures other than those described. One sister had suffered a fracture of the clavicle in an accident but no other fractures in the family were recalled.

CASE 8 R O'C C H C 4008 This girl, born of Irish parentage on October 24, 1930, was first seen at the Children's Hospital on June 14, 1937. She had large tonsils and an uneventful tonsillectomy was performed on July 18, 1937. On September 3, 1937, she fell about a foot while playing on a small tree stump, injuring the left arm and crying with pain for 2 hours. The x ray examination the

December 1940 February 4, 1941 April 8, 1941

Fig. 3. Case. Recurrent fractures of the left radius and ulna occurring in a 9 year old boy after an interval of 4 months and 1 week. The healing of the first fracture was complete by ray films February 4, 1941 and by clinical examination, and free use of the part was regained. The different character of the new fracture lines at the old fracture sites as well shown.

next day showed transverse greenstick fractures in the middle thirds of the radial and ulnar shafts with slight palmar angulation at the fracture sites. After the immobilization in plaster dressing was applied for 6 weeks satisfactory use of the part was obtained but for some time there was tenderness about the fracture sites and for a long time the part could ache during inclement weather. Even on her recovery seemed complete her mother noted that she would tend to protect that arm. A second injury occurred on November 4, 1940, when she was struck in the posterior aspect of the lower part of the left upper arm. Swelling and ecchymosis appeared, and there was pain for a few days but the x-ray studies are negative and there was no observed to be abnormal appearance of the bone structure at the old fracture sites, with no deformity. The arm was carried in sling for 3 weeks, and good recovery was obtained.

On November 22, 1940, she fell on a 4 feet while playing on the edge of a sand pit, again injuring the left forearm, and there was immediate severe pain causing her to cry for hours. The pain persisted and on December 3, 1940 she came to the clinic for x-ray studies. These showed a soft perosteal shadow about the middle third of the radial shaft at the old fracture site and a very slight disturbance in the bone structure such as not present at the examination of November 6, 1939. Re-examination on December 28, 1940, showed some resorption and increased density of the perosteal deposits and the irregularity of the bone structure as seen. Little more clearly so that there was no reasonable doubt that a second fracture of a very limited subperiosteal type had occurred at the old fracture site.

At the interview of December 28, 1940, there was no complaint of pain and she exhibited free use of the arm,

although her mother said that there was sometimes pain at night requiring hot water bottle. She had sustained no other fractures nor were there fractures in any of 4 siblings. Her appetite had been generally poor and she could take for meat or vegetables. She was decidedly thinner and less robust than her healthy brothers and sisters. Her height at this time was 56 kilograms for height of 35 centimeters. The ligaments about the joints showed more than the usual flexibility and the sclerae appeared thin with bluish cast. There was no deafness.

CASE 9. N. McK. A white girl born on March 25, 1931, and living in comfortable circumstances, tripped over her rubber while running on playground at school and fell on her extended right arm on November 20, 1940. She was referred to us a few hours later as private patient of Dr. Charles Kennedy and the x-ray examination disclosed greenstick fractures of the radius and ulna near the junction of their middle and distal thirds with sharp anterior and medial angulation at the fracture sites. Under ether anesthesia the normal alignment was restored, and plaster dressing was applied. Re-examination 14 days after the injury showed the fragments in close end to end approximation with an excellent alignment on both planes. The immobilization was maintained for 4 weeks and then as discontinued temporarily for early physiotherapeutic measures, extending over a period of 3 days, when the cast was discarded entirely. Convalescence was complicated at this point by an attack of chickenpox, but the normal use of the right arm was regained and there was no complaint or deformity of any kind.

On March 1, 1941, while roller skating she fell again on the right arm and sustained marked deformity as before. Re-examination of the old fracture sites was demonstrated on the ray films but with slightly different character and configuration of the fracture lines. There was again marked angulation toward the radial and ulnar aspects.

At an interview on this date she was observed to be fairly well nourished blond girl of pleasing appearance and weighing 7 kilograms with height of 35 centimeters. The arms and legs were quite thin and there was more than the usual flexibility at the joints. Her mother described her as "poor eater" taking food very slowly and having an aversion to meat. She liked variety of appetizers, however and drank three glasses of milk daily. The sclerae were blue and there was no deafness. The patient had sustained no fractures other than those described and none had been experienced by her mother or 4 sisters. Her father has been involved in accidents with fractures of the nose and at the ankle.

CASE 10. E. W. This girl, private patient of Dr. Darling of Pontiac, Michigan, was born on June 8, 1936. On June 7, 1940, while playing out of doors she jumped on a bench which tipped over and she was thrown to the ground on her outstretched left arm. Fractures of both bones of the forearm occurred, the ulnar fracture being quite oblique, with the end of the proximal fragment perforating the skin. X-ray studies (Fig. 4) on the same day showed the fractures with angulation anteriorly and toward the radial side particularly at the ulnar fracture site.

The deformity was reduced by manipulation and plaster dressing was applied and kept on for 6 weeks. The arm was markedly atrophied and remained thinner than the right one until the time of the second injury. There was no pain or other deformity, however, and the arm was used quite freely except for some slight limitation of pronation and supination. The puncture wound in the skin healed well and there were no signs of inflammation or infection.

She attended school during the autumn in good health and engaged in all of the usual activities. On February 9,

Fig 14 Case 12 Recurrent fracture of the clavicle in a 2 year old boy after an interval of 2 years and 2 months The first fracture occurred at birth and was observed to have healed without deformity in a study of the chest on February 22, 1940 The peculiar character of the second fracture line is well shown

1941, she went skiing and again injured the left forearm. X ray studies on the same day showed new fractures of both radius and ulna at the old fracture sites. There had apparently been complete healing at the old fracture sites with the formation of dense bone. The recent fracture lines had a different character and configuration than the first ones and resembled those seen in "brittle bones." Whereas the first fracture of the ulna was oblique the present one was transverse. No disalignment was demonstrable at this time except for the slight angulation of the ulnar fragments toward the radius with the former fracture well healed.

At an interview on March 10, 1941, she was seen to be a rather thin and pale girl weighing 46 kilograms with a height of 164 centimeters. There was an unusual degree of mobility at the joints but the sclerae were white and there was no deafness. Her mother described her appetite as very poor and she had always been smaller for her age than her two sisters. She disliked meat and could not eat eggs. There was a moderate intake of milk and fruit and small amounts of vegetables. The only fracture other than those described was one involving the right clavicle at the age of 7. No fractures had been experienced by the two sisters or either parent.

CASE 11 R DeT, C H F 8266 This boy was born of Italian parentage on October 5, 1931, and on December 1, 1940, while sledding placed his extended left arm against a tree to avoid hitting it and felt something snap. There was considerable deformity of the forearm and the x ray

examination a few hours later revealed fractures in the middle thirds of the radial and ulnar shafts (Fig 13). After several attempts at manipulation over a period of 6 days, the fragments were finally brought into a satisfactory position and alignment, as viewed in both planes. The history and physical examination at this time disclosed that he had been breast fed in infancy and had had no cod liver oil and very little orange juice. The tonsils were described as large and irregular and the teeth poor. There was no anemia—hemoglobin 13.7 grams/100 cubic centimeters—and the tuberculin and Kline tests were negative. The elbow and wrist joints were immobilized in plaster until February 4, 1941, and the arm was kept in a sling for another 2 weeks. The x ray examination of February 4, 1941, showed the alignment excellent in both planes with solid bony union occurring at both fracture sites. On March 11, 1941, the fracture was considered healed with a "good result."

The arm was used without pain or disability and neither the child nor his mother observed any difference in the size or alignment of the two arms. In March he played baseball pitching for a 4 man team which won the game. He also engaged in other sports, especially fighting, and his mother stated that he was always active as before. On April 8, 1941, while chasing a girl in a fight at school, he fell on his outstretched left arm and sustained another injury. X ray studies showed new fractures of the radius and ulna at the old fracture sites. The character and configuration of the fracture lines were quite different at this

December 9, 1940 February 4, 1941 April 8, 1941

Fig. 3. Case 1. Recurrent fractures of the left radius and ulna occurring in a 9-year-old boy after an interval of 4 months and 1 week. The healing of the first fracture was complete by ray films February 4, 1941 and by clinical examination, and free use of the part was regained. The different character of the new fracture lines to the old fracture sites is well shown.

next day showed transverse greenstick fractures in the middle thirds of the radial and ulnar shafts. With slight palmar angulation at the fracture sites. After manipulation, plaster dressing was applied for 6 weeks. Satisfactory use of the part was obtained but for some time there was tenderness about the fracture sites and for a long time the part could ache during inclement weather. Even when recovery seemed complete her mother noted that she could tend to protect that arm. A second injury occurred on November 4, 1940. When she was struck in the posterior aspect of the lower part of the left upper arm. Swelling and ecchymosis appeared, and there was pain for several days but the ray studies are negative and there is observed to be a normal appearance of the bone structure at the old fracture sites, with no deformity. The arm was carried in sling for 3 weeks and good recovery was obtained.

On November 2, 1940, she fell from 14 feet while play-fing on the edge of a mud pit, again injuring the left forearm, and there was immediate severe pain causing her to cry for hours. The pain persisted and on December 3, 1940, she came to the clinic for ray studies. These showed soft periosteal shadow about the middle third of the radial shaft at the old fracture site and a very slight disturbance in the bone structure, which was not present at the examination of November 6, 1940. Re-examination on December 28, 1940, showed some resolution and increased density of the periosteal deposits and the irregularity of the bone structure as seen little more clearly so that there is no reasonable doubt that a second fracture of a very limited subperiosteal type had occurred at the old fracture site.

At the interview of December 9, 1940, there was no complaint of pain and she exhibited free use of the arm,

although her mother said that there was sometimes pain at night requiring hot water bottle. She had sustained no other fractures nor were there fractures in any of 4 siblings. Her appetite had been generally poor and she cared little for meat or vegetables. She was decidedly thinner and less robust than her healthy brothers and sisters. Her weight at this time was 36 kilograms for height of 135 centimeters. The ligaments about the joints showed more than the usual flexibility and the sclerae appeared thin with bluish cast. There was no deafness.

CASE 9. MCK. A little girl born on March 5, 1935, and living in comfortable circumstances, tripped over her rubber ball running on playground at school and left on her extended right arm on November 20, 1940. She was referred to us a few hours later as private patient of Dr. Charles Kennedy and the x-ray examination showed greenstick fractures of the radius and ulna near the junction of their middle and distal thirds. With sharp anterior and medial angulation to the fracture sites. Under ether anesthesia the normal alignment was restored, and plaster dressing was applied. Re-examination 14 days later showed the fragments in close end-to-end approximation with an excellent alignment in both planes. The immobilization was continued for 4 weeks and then was discontinued temporarily for early physiotherapeutic measures, extending over period of 3 days, but the cast was discarded entirely. Convalescence was complicated at this point by an attack of chickenpox, but the normal use of the right arm was regained and there was no complaint or deformity of any kind.

On March 19, 1941, while roller skating she fell again on the right arm and sustained marked deformity as before. Refractures at the old fracture sites are demonstrated on the ray films but with slightly different character and configuration of the fracture lines. There was again marked angulation toward the radial and ulnar aspects.

At an interview on this date she was observed to be fairly well nourished blond girl of pleasing appearance and weighing 37 kilograms. Her height of 135 centimeters. The arms and legs are quite thin and there is more than the usual flexibility at the joints. Her mother described her as "poor eater" taking food very slowly and having an aversion to meat. She liked variety of vegetables, however and drank three glasses of milk daily. The sclerae were white and there was no deafness. The patient had sustained no fractures other than those described and now had been experienced by her mother for 4 years. Her father has been involved in accidents with fractures of the nose and the ankle.

CASE 10. E. W. This girl, private patient of Dr. Darling of Pontiac, Michigan, was born on June 8, 1940. On June 27, 1940, while playing out of doors she jumped on a bench which tipped over and she was thrown to the ground on her outstretched left arm. Fractures of both bones of the forearm occurred, the ulnar fracture being quite oblique, with the end of the proximal fragment perforating the skin. X-ray studies (Fig. 1) on the same day showed the fractures. With angulation anteriorly and toward the radial side particularly at the ulnar fracture site.

The deformity as reduced by manipulation and plaster dressing was applied and kept on for 8 weeks. The arm was markedly trophic and remained thinner than the right one until the time of the second injury. There was no pain or other deformity however, and the arm was used quite freely except for some slight limitation of pronation and supination. The fracture wound at the skin healed well and there were no signs of inflammation or infection.

She attended school during the autumn in good health and engaged in all of the usual activities. On February 8,

Fig 14 Case 12 Recurrent fracture of the clavicle in a 2 year old boy after an interval of 2 years and 2 months The first fracture occurred at birth and was observed to have healed without deformity in a study of the chest on February 22, 1940 The peculiar character of the second fracture line is well shown

1941, she went sking and again injured the left forearm. X ray studies on the same day showed new fractures of both radius and ulna at the old fracture sites. There had apparently been complete healing at the old fracture sites with the formation of dense bone. The recent fracture lines had a different character and configuration than the first ones and resembled those seen in "brittle bones." Whereas the first fracture of the ulna was oblique the present one was transverse. No disalignment was demonstrable at this time except for the slight angulation of the ulnar fragments toward the radius with the former fracture well healed.

At an interview on March 10, 1941, she was seen to be a rather thin and pale girl weighing 46 kilograms with a height of 164 centimeters. There was an unusual degree of mobility at the joints but the sclerae were white and there was no deafness. Her mother described her appetite as very poor and she had always been smaller for her age than her two sisters. She disliked meat and could not eat eggs. There was a moderate intake of milk and fruit and small amounts of vegetables. The only fracture other than those described was one involving the right clavicle at the age of 7. No fractures had been experienced by the two sisters or either parent.

CASE 11 R DeT, C H F 8266 This boy was born of Italian parentage on October 5, 1931, and on December 1, 1940, while sledding placed his extended left arm against a tree to avoid hitting it and felt something snap. There was considerable deformity of the forearm and the x-ray

examination a few hours later revealed fractures in the middle thirds of the radial and ulnar shafts (Fig 13). After several attempts at manipulation over a period of 6 days, the fragments were finally brought into a satisfactory position and alignment as viewed in both planes. The history and physical examination at this time disclosed that he had been breast fed in infancy and had had no cod liver oil and very little orange juice. The tonsils were described as large and irregular and the teeth poor. There was no anemia—hemoglobin 13.7 grams/100 cubic centimeters—and the tuberculin and Kline tests were negative. The elbow and wrist joints were immobilized in plaster until February 4, 1941, and the arm was kept in a sling for another 2 weeks. The x ray examination of February 4, 1941, showed the alignment excellent in both planes with solid bony union occurring at both fracture sites. On March 11, 1941, the fracture was considered healed with a "good result."

The arm was used without pain or disability and neither the child nor his mother observed any difference in the size or alignment of the two arms. In March he played baseball pitching for a 4 man team which won the game. He also engaged in other sports, especially fighting, and his mother stated that he was always active as before. On April 8, 1941, while chasing a girl in a fight at school, he fell on his outstretched left arm and sustained another injury. X-ray studies showed new fractures of the radius and ulna at the old fracture sites. The character and configuration of the fracture lines were quite different at this

(time, however. The bone, although dense appeared to lack normal structure and the appearance of the fracture lines indicated an increased fragility.

At an interview on April 9, 31, he was seen to be an active child with thin, waxy extremities. There was little more than the usual flexibility of the ligaments about the joints and the sclerae were distinctly bluish, but there was no deafness. He weighed 26 kilograms and measured 27 centimeters in height. He had had no other fractures than those described and none was known in the parents or 4 other siblings. His mother described his appetite as good, with generous intake of eggs, vegetables, and meat, with fruit of some kind daily.

CASE. M. L., C. H. D 9432. This boy was born of Sicilian parentage on October 1933, as one of pair of twins. There was cephalic presentation and delivery

seemed to be uncomplicated, but weeks later deformity of the left clavicle was noted. The x-ray examination on October 5, 33, showed fracture without displacement of the fragments in the middle third of the clavicle with large amount of callus at the fracture site. No treatment was advised, and in due course complete recovery occurred with free use of the arm and no sign of discomfort.

He suffered from frequent upper respiratory infections and was seen many times on this account in the Out Patient Department. On March 6, 30, he fell about 3 feet, sustaining fracture of the right parietal bone. Recovery was complicated by meningitis for which bilateral mastoidectomy was performed. On February 2, 30, in the course of an upper respiratory infection, an x-ray study was made of the chest which incidentally revealed complete healing with normal appearance of the bone

structure and no deformity at the old fracture site in the left clavicle

On December 11, 1940, he tripped while running with his twin brother and fell on his left shoulder with his arm beneath him. There was evident pain on lifting his left arm. An x ray examination on the same day revealed a simple transverse fracture line at the old fracture site. Any question as to the presence of a recent injury was answered by a re-examination on January 4, 1941, which showed a large amount of soft callus at the fracture site.

At an interview on this date the child was found to have a weight of 10 kilograms for a height of 83 centimeters. He seemed well nourished and his appetite was said to be excellent for a variety of foods. He had sustained no fractures other than those described and no fractures were recalled in the parents or in five siblings with the exception that one other child had sustained a fracture of the clavicle at birth. The sclerae were distinctly bluish and there was considerable flexibility of the ligaments but no sign of deafness.

CASE 13 B A, C H E 2202 This girl was born of Polish parentage on August 5, 1937, and was first seen at the Children's Hospital on March 22, 1939, following a fall on some steps which produced an injury to the right shoulder. The roentgen ray examination demonstrated a fracture of the clavicle near the junction of the proximal and middle thirds with the usual deformity. A dressing was applied for immobilization and maintained for 6 weeks. At the roentgen ray study of May 3, 1939, it was observed that osseous union was occurring with a large amount of

dense callus and with some overriding of the fragments, the distal end of the proximal fragment being displaced upward. After the dressing was removed, the child favored the right arm for a short period but she soon exhibited her normal right handedness, and there was no complaint or disability of any kind. The mother noted a lump at the fracture site but this disappeared in 1 or 2 months with no residual deformity. She experienced mild whooping cough in the spring of 1939 and chickenpox in the summer of 1940. She had suffered from eczema since birth and at 1 year of age was placed on a vegetable-poor diet for 6 months without benefit. There had been occasional colds and on December 24, 1939, she was hospitalized for nasopharyngitis, otitis media, and cervical adenitis.

On February 14, 1941, she fell from a couch and sustained a heavy blow to the right shoulder. Roentgen ray study revealed a new fracture without displacement or disalignment of the fragments at the old fracture site. There was otherwise a normal appearance of the bone structure and the old fracture had apparently healed completely and without deformity.

On February 14, 1941, she fell from a couch and sustained a heavy blow to the right shoulder. Roentgen ray study revealed a new fracture without displacement or disarrangement of the fragments at the old fracture site. There was otherwise a normal appearance of the bone structure and the old fracture had apparently healed completely and without deformity.

September 5, 1930.

Fig. 30. Case 7. T. view of the right forearm of an 7-year-old negro boy showing recent fractures in the middle thirds of the radius and ulna. With dense bone structure in the cancellous portion of the radius proximal to the distal epiphysis at the site of fracture which had occurred 3 months before.

At an interview at the time of the second fracture she was found to weigh 5.5 kilograms with height of 95 centimeters and appeared well nourished although her mother said she had poor appetite. She disliked meat but could eat milk, eggs, and vegetables. She was described as being very active with many falls and bruises but rarely any serious injury. She had sustained only the two fractures described, and there was no history of fracture in the parents or sister. The sclerae were considerably bluish but there was normal flexibility of the joints and no deafness was evident.

CASE 14. H. S. C. H. 8900. A Jewish boy born on October 30, 1923, as seen in the Children's Hospital in 1923 and 1924 for various minor complaints including feeding problems. On June 8, 1925, he fell from a parked automobile and the right knee was noted to be tender. X-ray examination revealed a greenstick type injury of the tibia just beneath the proximal epiphyseal line (Fig. 6). There was no significant displacement or dislocation of the fragments and plaster cast as applied. Due to the mother's illness the child was not brought back for further care. After 6 weeks the cast fell off spontaneously. "Sores" and big blisters were seen on the leg and foot, and after many months of household remedies healing took place and normal use of the part was obtained. He became a very active child, indulging in violent games and sustaining many mild injuries. In August, 1927, he was treated for limited injury at the lower end of the left radius.

On November 24, 1929, while playing football, he fell striking his knee in the ground and again injured the right knee area. X-ray studies showed fracture lines at the proximal end of the tibial diaphysis in otherwise apparently normal bone structure. Healing took place in satisfactory manner with no resultant deformity or disability.

At an interview on November 30, 1930, he was observed to be well developed and nourished boy weighing 20 kilograms and with height of 115 centimeters. His mother stated, however, that he had been less well nourished in the past and as "funny" eater usually going without breakfasts and eating very little meat. The only other history of fracture in the family was in one brother who had sustained two fractures of the forearm. The patient's sclerae appeared normal and there was no deafness or hyperextensibility at the joints.

CASE 5. A. G. 8500. 8 years of age, private patient of Dr. J. O. Koppel. In April, 1927, while playing baseball, he turned his foot on first base. He was able to walk for 10 days but with much pain and on April 5, 1927, X-ray studies (Fig. 8) were made revealing fracture at the base of the fifth metatarsal bone. A plaster cast was applied for 3 weeks, and subsequently he was able to walk without disability.

In September, 1927, on jumping over a fence he felt something snap in the left foot. X-ray studies showed a new fracture in the fifth metatarsal bone and cast was applied for 4 weeks. There was satisfactory recovery and he was able to walk without pain or other disability.

One night in February 1928, he injured his left foot for the third time when he tripped over a wire in the dark. X-rays again showed the appearance of a new fracture and cast was applied for 4 weeks. Recovery was satisfactory as before.

When interviewed in September, 1930, he was having no pain or difficulty in walking and roentgenograms revealed complete healing of the old fractures. He was observed to be large, obese boy weighing 41 kilograms with height of 85 centimeters. There was no deafness and the sclerae were hazy but there was somewhat more than the normal mobility of the joints. He was not aware of having sustained any other fractures than those described in the left fifth metatarsal bone.

CASE 6. R. O. C. H. D 650. This boy born on June 5, 1924, fell 3 or 4 feet to the ground from a porch on September 9, 1926, and sustained an injury to the right lower forearm. A diagnosis of fracture was made by the family physician. About an X-ray examination and splints were applied for 4 weeks. A good result was obtained with no further trouble until July 2, 1930, when he fell on his outstretched arm and hand while playing on a tree stump and again injured the right forearm. Pain persisted and small areas of ecchymoses appeared. An X-ray examination (Fig. 9) at the Children's Hospital 2 weeks after the injury revealed evidence of the old completely healed fracture at the lower end of the radial diaphysis and a more recent fracture of the radial shaft near the junction of the proximal and middle thirds. A plaster dressing was applied and retained for about 3 weeks, and the normal use of the arm was regained.

CASE 7. R. C. C. H. 70540. A colored boy born of epileptic parents on June 24, 1920, as seen in the Children's Hospital on many occasions for minor complaints. On June 9, 1930, he fell on his right hand and a greenstick fracture of the lower end of the radius, 10 centimeters proximal to the lower epiphyseal line, was demonstrated by X-ray. There was slight buckling of the cortex posteriorly but there was no important displacement or dislocation. Treatment consisted in immobilization in plaster for

number of weeks and a satisfactory result was obtained. On September 5, 1940, he fell on his outstretched hands while riding a bicycle and felt a sharp pain in the right forearm. X-ray studies showed complete healing at the old fracture site with new fractures in the shafts of the radius and ulna near the junction of their middle and distal thirds. After unsuccessful attempts to reduce the deformity by manipulation, an open operation was carried out with a satisfactory approximation of the fragments and a good final result.

IMPLANTATION OF URETERS INTO THE RECTOSIGMOID WITH A STUDY OF THE POSTOPERATIVE COURSE

EDGAR J. POHL, Ph D., M D., Baltimore, Maryland

DURING the past few years, numerous attempts have been made to improve upon old methods (5) and to devise new techniques (1, 3, 4, 6, 9) for the implantation of ureters into the rectosigmoid. Obviously, it is unphysiological to divert the urinary stream into the large bowel where the normal constituents of the urine will be acted upon by the ferments and bacteria of the intestinal tract. However, one is forced to form this outlet in certain instances of developmental anomalies of the bladder, or in cases in which the bladder must be removed because of malignancy or other disease.

The most important considerations in such an implantation are that the opening of the ureter into the bowel be adequate, pliable, and free of surrounding fibrosis, and that the ureter lie in the wall of the bowel for a distance before opening into the lumen of the intestine. Coffey demonstrated that this intramural segment acts as a check-valve to prevent the retrograde passage of material up the ureter when the bowel contracts. Since the intestinal contents are liquid after the implantation of the ureter and the delivery of urine into the intestine, it is particularly important that this valve function well so as to exclude the highly infectious material from the urinary tract. The most efficient check valve is ensured when healing between ureter and bowel occurs in a surgically clean bed, which is accomplished in a technique described by the author. The ureter has a fibrous tissue covering which is laid directly on the fibrous submucosa of the intestine. Infection in such an anatomical environment predisposes to excessive development of scar tissue, which will result in a stiff intramural tube, and will function poorly as a check valve against retrograde flow of fluid into the ureter. Furthermore, during the healing following the first stage, there is edema of the tissues involved, and they cannot respond to changes of pressure in the bowel. During this 10 day period it is important that the ureter shall not be open into the lumen

of the bowel, if retrograde passage of contaminated material up the ureter is not to occur and initiate a serious infection of the upper urinary tract. To have a properly functioning valve is considered of sufficient importance to justify an additional operative procedure when possible. The operation of implantation of the ureter is divided into two stages, in the first stage the ureter is embedded in the wall of the bowel without interruption or diversion of the urinary stream, and in the second stage the opening is made between the ureter and the bowel with diversion of the urinary stream into the intestine.

This unphysiological formation of a cloaca gives rise to a number of abnormalities, especially in the dog. Since this animal stands on all fours, his large bowel is in a practically horizontal position, and this position, coupled with the fact that in

Fig. 1. First stage. Illustrates in section of rectosigmoid down to submucosa with the preservation of the blood vessel, and shows the right ureter exposed and developed for implantation into the bed in the bowel.

From the Surgical-Histological Laboratory, Department of Surgery, The Johns Hopkins University School of Medicine. Reprint requests of this work should be made to the Department of Surgery, Stanford University School of Medicine, San Francisco, California.

Fig. 2. First stage. a, Method by which the ureter is embedded into wall of bowel by means of continuous Lembert or Cushing suture of No. 3 chrome catgut. Subincision is left showing at both ends to avoid compression of the ureter. b, Manner in which cut edge of peritoneum is sutured over the implanted ureter. This obviates kinking of the ureter as it goes from its usual retroperitoneal location to its new bed in the wall of the rectosigmoid. Ten weeks are allowed for healing before the second stage of the operation is undertaken. Silk should not be used to close the intestinal bed because it frequently cuts through the underlying ureter even though interrupted sutures are employed.

the dog the large bowel has no well developed valves or folds but is rather straight to be allows the fluid material resulting from the admixture with urine to flow upward to the ileocecal valve or even higher and gives rise to much reabsorption. This reabsorbed material appears to be rather toxic and results in a secondary anemia.

OPERATIVE PROCEDURES

In the course of this and previous studies numerous operative techniques have been used. When the single stage procedure is used in which the ureter is embedded in the wall of the bowel and the opening between ureter and bowel is made as advocated by Coffey, Mayo and Hinman (6) the survival rate is 5 to 10 per cent if both ureters are embedded at the same time. Death results from leakage, infection of the operative bed and peritonitis. In my hands, with the

technique advocated by Higgins, there was a mortality of approximately 35 per cent in the first stage from leakage and infection. The mortality in the two stage procedure previously described by the author and the modification here presented was less than 5 per cent in the experimental animal. These deaths were not due to leakage, infection or peritonitis, but were due to the small size of the structures resulting in technical difficulties and tearing of the ureter. Although the technique originally described by the author is entirely satisfactory for the experimental animal it cannot always be applied to the human being because the pressures of large tumors in the bladder or elsewhere pressing on the bowel may make it impossible to pass the proctoscope in the second stage. Although this technique is preferred whenever it is applicable a second method has been developed for those cases in which the proctoscope cannot be inserted. The first stage is

Fig 3 Second stage Two weeks have elapsed between first and second stages to permit aseptic healing of the ureter in its intramural location a An assembly of the cutting device consisting of a heavy darning needle mounted with a length of No 26 B & S gauge nichrome wire and a traction suture of fine braided silk. This will serve as the cutting instrument to connect the lumina of ureter and bowel b, The cutting assembly being introduced into the ureter c, Same as b in cross section

essentially unchanged The second stage is not an entirely aseptic procedure, however, the most important healing of the ureter in its intramural bed has already occurred in a clean field If gross

soiling should occur at the second stage, the bladder should be removed at a later date The operation of ureteral transplantation on a debilitated human being is a considerable undertaking, and

Fig. 6 A heavy rolled glass tube placed over one limb of the cautery to protect the ureter. A high cautery current is used in order that cutting will proceed rapidly as the instrument is withdrawn. The ureter has been placed cut slit about 5 centimeters long connecting the ureter and bowel.

one should be prepared to perform it in multiple stages and not to do too much at one time. The technical procedure can be readily followed in the illustrations.

THE UNPHYSIOLOGICAL STATE

Again it must be said that the dog is a poor experimental subject for ureterointestinal anastomosis. He walks on all fours, there are no valves in the large bowel, and he has a strong anal sphincter and a heavy well developed bowel musculature. The heavy bowel musculature causes a slight dilatation of the ureter above the implantation. This dilatation and obstruction is not sufficient to be demonstrable by intravenous

Fig. 7 The incision completed, the distal end of ureter is located, cut short and inverted into bowel. The opening in the bowel is ordinarily closed with single mattress suture. The area is covered with peritoneum as indicated.

urography. This change moreover, is not due to the ureters being subjected to the intraintestinal pressure because it develops even though the first stage only is done. The anthropological and anatomical arrangement of the dog is very excessive absorption of the urinary constituents from the bowel following ureterointestinal anastomosis. It is likely that some of the substances contained in the urine are altered by the bacterial flora and the ferments in the bowel before they are reabsorbed. After transplantation of the ureters into the rectosigmoid the excrement from the bowel has a strong ammoniacal odor.

Although it has not been proved it is believed that the ammonia liberated by the urease acting on the urea of the urine excreted into the bowel is absorbed and acts as the toxic substance. A secondary anemia develops which does not seem to result from the increase in blood urea *per se*. The usual course of blood urea and hemoglobin levels are illustrated in Figure 8. Within 2 weeks after the first stage of the operation, nonprotein nitrogen blood level and the hemoglobin return to normal and would remain unchanged indefinitely. Following the second stage however when urine is being discharged into the bowel, there is a moderate and immediate rise in the nonprotein nitrogen level of the blood. After this immediate change the percentage of nonprotein nitrogen remains essentially constant, except for occasional

Fig 8 This chart illustrates the characteristic course of the nonprotein nitrogen (solid dots—mgm per cent) and hemoglobin levels (circles per cent) as observed in a series of 44 animals. Eventually all animals die following a sudden rise in nonprotein nitrogen and rapid fall in hemoglobin. Animals frequently survive for 6 to 8 months.

Fig 9 This chart illustrates the characteristic course of the nonprotein nitrogen (solid dots) and hemoglobin levels (circles) as observed in a series of 20 animals. Half of these animals were subjected to the first stage of the operation only, and the other half were operated upon twice as indicated, and their subsequent course is plotted by the dotted lines. The sudden increase in nonprotein nitrogen and the rapid decrease in hemoglobin occur only when the second

stage of the operation is done and urine is delivered into the large bowel. In all of these animals loose bands of cellophane or silk were placed around both ureters at the time of the first stage of the operation. These bands caused a gradual constriction of the ureters of the dogs. Animals have been known to tolerate for long periods of time a high nonprotein nitrogen blood level that is caused by simple obstruction.

periodic fluctuations, until the development of a rather severe secondary anemia. Following the establishment of an opening between the ureter and the bowel, the hemoglobin falls progressively and at a regular rate until it reaches 40 to 50 per cent. Up to this time the animal appears normal. There is then a sudden change, the animal refuses to eat, the rate of the hemoglobin fall increases, and the nonprotein nitrogen rises abruptly. Death, frequently accompanied by a *Bacillus coli* septicemia, occurs within a week. Necropsy shows the opening between ureter and bowel to be patent and soft, and the upper urinary tract is essentially normal both grossly and microscopically. Apparently the fall in hemoglobin is not dependent upon the nonprotein nitrogen level of the blood. In a group of 20 animals bands of cellophane or silk were, at the time of the first operative stage,

placed loosely around both ureters proximal to the implant. These animals show the usual immediate elevation of blood urea, with return to normal for a period of weeks, and then, with the gradual development of fibrosis in the region of the bands and constriction of the ureters, the nonprotein nitrogen of the blood rises slowly to high levels. During this time there is but a slight drop in hemoglobin. If on alternate animals, however, the second stage of the operation to deliver urine into the bowel is performed, the courses followed by the two groups are entirely different. From the difference in the blood pictures of the two groups, as illustrated in Figure 9 it appears that the nonprotein nitrogen blood level is not responsible for the anemia, but rather that substances are being absorbed from the bowel which react to cause this and other changes.

Whether this intoxication is due to the absorption of ammonia from the bowel for resynthesis into urea by the liver which in turn is re-excreted by the kidney to establish a vicious cycle has not been proved but is postulated as a possible reasonable explanation of the anemia and the death of the animals.

EVALUATION

The marked rise in blood urea following the bilateral embedding of ureters in the first stage demonstrates conclusively that both ureters should not be embedded simultaneously in a debilitated person with a high initial blood urea. If preoperative intravenous urography shows the ureters to be greatly dilated it must be appreciated that these enlarged structures cannot be successfully buried in the wall of the bowel. Under these circumstances it is well to consider nephrostomy as recommended by Cabot and to allow sufficient time for the ureters to decrease in size and for the kidney function to improve. Nephrostomy followed by the simultaneous embedding of both ureters is a simpler safer and more satisfactory procedure than dealing with the ureters singly. The use of ureteral catheters during this period has been suggested, but this may be impossible mechanically and catheters are poorly tolerated in the presence of the infection frequently found in urinary stasis.

In view of the rise of blood urea and the fall of hemoglobin and their apparent association with the reabsorption of toxic products following the delivery of urine into the rectosigmoid, it is suggested that the patient be placed in the semi-Fowler position as soon as practical after operation that a small rectal tube be inserted just

beyond the sphincter ani and that he be encouraged to evacuate the bowel frequently. Jewett induced the anal sphincter of dogs to facilitate emptying the bowel.

Frequent hemoglobin determinations should be done. While in bed, the patient should assume the semi-Fowler position and be awakened once at night to empty the bowel. Mild catharsis may be indicated.

It cannot be repeated too frequently that the healing following embedding of the ureter in the wall of the bowel should occur in the absence of infection in order to ensure a patent orifice and a soft, readily compressed intramural bed for the ureter.

SUMMARY

1. An alternative procedure is presented for the second stage of the operation for ureterointestinal anastomosis.

2. The unphysiological state created by the formation of an abnormal clasp is discussed.

3. A secondary anemia following ureterointestinal anastomosis is reported.

4. The cause of late death of the experimental animals is considered.

INTERNAL WIRE FIXATION FOR FRACTURES OF JAW ✓

Preliminary Report

JAMES BARRETT BROWN, M D , F A C S , and FRANK McDOWELL, M D ,
St Louis, Missouri

IN some fractures of the lower jaw, in which interdental wiring cannot be done, a wire—of the Kirschner type—drilled across the fracture line may be an easy and satisfactory method of treatment

The indication for this internal fixation may be present when the opportune early time for interdental fixation has passed and the fragments have become displaced, with compounding into the mouth, infection, and local sloughing. It also may

From the Department of Surgery Washington University School of Medicine

be considered in edentulous jaws, when there is much comminution and accompanying injury, as in gunshot and war injuries, when many teeth have been loosened or broken, in displaced symphysis fractures, and in fractures at the angle in which the posterior fragment is pulled out and up into the upper buccal fornix by the closing muscles (Fig 3). This last deformity is one of the worst to contend with, and, if left uncorrected, may result in non-union of the fragments. It may also prove to be of value in certain separations of the upper jaw

Fig 1. Bad comminution at symphysis with only small points of bone in contact, left condyle and many teeth broken. Fixation at symphysis with one internal wire and a

second plane of fixation obtained with an anterior wire arch. Jaws wired together because of the condyle fracture opened after 4 weeks with internal wire still in place

Fig. 2. Comminuted fracture near symphysis, seen after days, the unsuccessful interdental wiring, infection, and local sloughing. Both condyles also are broken, and many teeth are loosened. Fixation at symphysis with internal brace. Inferior dental wire arch and trap to upper jaw added because of condyle fractures.

The internal wire will insure fixation in one plane—that is, the fragments cannot slip up or down past each other. However they might rotate in or out, or they might pull apart and, therefore *the addition of an anterior wire dental arch* will give a second plane of fixation that will prevent rotation and will jam the fragments in impaction so that separation will not occur. If there is a condyle fracture to deal with also, or if normal occlusion cannot be maintained then there can be the *further addition of interdental fixation to the upper jaw*.

Multiple internal wires can be used for multiple fractures, or to give the second plane of fixation if desirable.

Protection of the nerve canal is advisable even though the nerve may have been cut in two by displacement of the fragments. The same is true of any good teeth and this can usually be done by staying below the canal. When a second wire is placed above the lower one there is more chance of damage of the nerve and teeth.

An electric power drill is practically necessary as the hand drill may not give enough speed for easy penetration of the bone. Regular Kirschner

wires may be used, but stainless steel wires, recommended by Dr. C. H. Crego in leg lengthening are cheaper and can be obtained in suitable lengths of thickness from .05 inch to .08 inch, a three-sided point being put on them. Bicycle and velocipede spokes also have been used by Dr. Crego.

A further modification is to cut threads all the way along an .08-inch wire with a No. 56 die which is a bicycle spoke threader and, after it has been drilled into position, screw regular bicycle spoke nipples or small nuts down against the bone to hold the fragments together. This threaded wire itself may give sufficient tightness without the nipples to prevent separation and is applicable to edentulous patients or any time the dental arch cannot be used (Fig. 4).

OPERATION

Local or deep block anesthesia is usually employed. The fragments are aligned with the hands,

*This wire is 18-8 stainless steel. The smallest size to give the necessary stiffness is preferable.

†It has been suggested by Dr. J. A. Brown that the threaded wire might be cut that end, have friction against the bone removed, and low cylinder could be slipped over an unthreaded wire down against the bone and held with set screw put in the end of

Fig 3 Fracture at angle with elevation of posterior fragment and loss of mandibular nerve sensation. Fixation with single internal wire put in from behind and below the nerve canal. Avoidance of open reduction or elastic traction reduction of posterior fragment. Interdental wiring was done because of second fracture in body. At right, mouth open, with wire in place.

or an open reduction may be necessary, an elevator being used between the fragments. It is important that reduction be accurate, as only slight adjustment is possible after the wire is in.

A puncture incision is made to get the wire in against the bone, and the wire and drill are lined up accurately. Then, perhaps most important of all, the fragments have to be held in accurate position with the hands while the wire is drilled into place. (Little mention need be made of the necessity of care with the drill and wire, and for avoidance of injury to the hands that are holding the fragments.) The wire usually is drilled on through the bone and a small opening is made to let it through the skin on other side. Secondary internal wires may be needed occasionally (Fig 2).

The interior arch wire is applied by putting No. 26 stainless steel wires on posterior teeth on each side, twisting the strands tightly for 2 inches, then twisting them together in midline and holding them with individual No. 28 wires around separate teeth. Any other type of arch appliance may be used, but this one requires no added equipment and is usually satisfactory.

This is the wire that should suffice for the second and final plane of fixation and should impact the fragments together over the internal wire (Figs 1, 2, and 4).

Interdental fixation is done as mentioned, if there is some final adjustment of occlusion to be secured or if the condyles also have been fractured. The jaws may be fastened directly together or by any effective method of elastic traction.

In edentulous jaws, when dental plates wired or bandaged in place with the mouth closed will not suffice, a single internal wire or a threaded one as shown in Figure 4 may be effective as the jaws are usually small from atrophy anyway. This plan for edentulous jaws seems much less trouble for the patient and surgeon than attempting any rigid fixation within the mouth with screws down into the bone and nerve canal.

Sulfanilamide is used locally in all open wounds and right in the fracture line if it has been separated widely enough to admit the powder. Wounds of the mouth, jaw, and neck, with their marked tendency to infection, make a field of great importance for the use of this drug.

Fig. 4. 8-8 stainless steel 1/8 in. of lock threaded with 2-50 die-cutter. Such is bicycle spoke-threader and with regular bicycle spoke nipples screwed on. (Equipment, courtesy Dr. Crego). In the patient shown, the fracture is

held with an internal threaded 1/8 in. and one nipple. The mouth could be opened easily after the operation, and soft food was taken. Anterior arch was put on to hold separate loose fragment.

Pressure dressings of soft cotton mechanics waste are applied to give support to the soft tissues and prevent, as far as possible, hematomas, hemorrhage, and swelling, and also to lend further support to the bone fragments.

The jaw seems solid immediately and the patient experiences the usual comfort of a set fracture. The ends of the wire are covered and the patients do not object much to discomfort. In some instances, the wires may be cut short enough to be covered by the skin, but it is probable that they all should be removed finally. Just one or two days are required in the hospital, and some patients can open the jaws and take soft foods almost immediately.

The removal of the wires can be done easily after 3 to 5 weeks, depending upon the progress. There may be some irritation around the wires but no serious osteomyelitis should develop.

This plan was thought to be new but articles on the subject were found by Ipsen and Sobyte in Denmark and Meade in Ireland, and these men seem to have been the only ones to have reported it.

In the voluminous literature from the last war and since then, there has been a multiplicity of dental splints, often with emphasis on some contrivance of little fundamental bearing. If this simple direct method of internal wire fixation by drilling wire across the fragments will help to rid the use of complicated dental splints, overhead plaster-cap traction for elevated posterior fragments, and wide open reductions, it will be worthwhile.

REACTION OF BONE TO METALS

II Lack of Correlation with Electrical Potentials

R T BOTHE, M S, M D, and H A DAVENPORT, M D, Chicago, Illinois

EXPERIMENTS in which as many as four different kinds of metals or alloys were implanted into the femurs of cats were reported in an earlier paper (Bothe, Beaton and Davenport, 1940). Differences in electrical potentials between a number of the implants were taken *in vivo* after a postoperative survival period of about 7 months and the reaction of the bone to the various metals was studied. The correlation between electrical potentials and bone reaction was not good, and in view of the emphasis that has been given to electrolysis, it was decided to make another series of implantation experiments to test the effect of electromotive force more accurately.

Some of the more pertinent references to experimental and clinical experiences with bone reactions to metals were cited in the preceding paper, and two more which deal with electrical phenomena can be mentioned here.

Berti-Riboli (1938) measured potentials between bone and metals at three different time intervals after applying plates to the long bones of rabbits and dogs. The method of making the measurement of the electromotive force between the bone and the plate is not made clear, but the difference of potential was found to diminish with time. Copper, aluminum, stainless steel (3 kinds), duraluminum and 20 carat gold were used, and there was a difference in the rate of diminution of potential for each metal. A hypothesis was proposed that the rate of diminution was directly proportional to the toxicity of the metal.

Hudack (1940) reported on the use of high chromium, low nickel stainless steel, and emphasized the necessity of polishing and of treating alloys with nitric acid to minimize the presence of foci for electrolytic corrosion.

It has seemed to us that too much emphasis has been placed on electrical effects and too little on the more general properties of the solubility of metals in body fluids and the reaction of tissues to the dissolution products. In order to test the influence of differences in electrical potential in contrast with characteristic properties of individual metals, we have implanted two instead of

four metals into each bone and have attempted to correlate reactions with electromotive force differences.

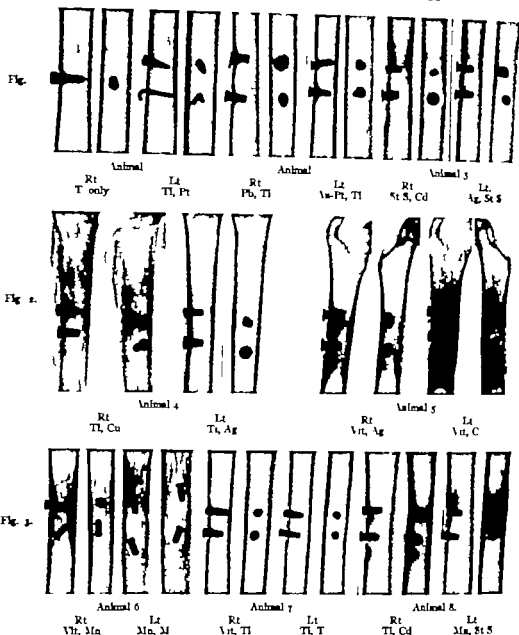

Experimental. One male and 16 female cats were used. Two implants, usually of different metals were made into each femur. The technique of making the implantation was the same as that used in the previous experiments. All 17 animals survived the experimental period, and were sacrificed at intervals between 186 and 329 days. Electrical potentials between the two implants, and also the potential from a copper electrode in the adjacent muscle to each implant, were measured while the animal was under anesthesia just prior to sacrifice. A few of the implants had become buried in the bone and potentials on them were not secured, and one had sloughed into adjacent soft tissue.

In arranging the pairs of metals, the object was to secure (1) pairs with rather large potential differences, (2) pairs with medium potential differences, and (3) pairs with little or no potential differences. The results are listed in Table I. A critical examination of the potential differences shows that they are not reproducible from animal to animal with the degree of accuracy that might be desired, but that the order of magnitude permits them to be grouped into low, medium, and high. The potentials have been correlated with the amount of bone reaction, and a recapitulation of the findings made in Table II.

RESULTS

It is seen in Table II that 7 of the metals or alloys reacted in the direction of their electrical differences while 10 did not. This is interpreted to mean that there is no direct correlation between a condition which predisposes to electrolysis and one which does not. Reactions occurred in the regions immediately surrounding the offending metal. However, had metallic ions been carried from one metal to the other as a result of electrical effects, we would expect to see reactions about both implants. In only one femur (cat 4, Fig. 2) which received titanium and copper, was the reaction so extensive that it spread far enough to make uncertain which one of the pair was the offending metal. Comparing this femur with the

From the Department of Anatomy Contribution No. 346 and the Division of Surgery Northwestern University Medical School

left one makes it evident that copper and not titanium is toxic, since titanium was not reactive when paired with silver or when used alone (cats 1 and 7). In the left femur of cat 5 the difference in potential between copper and vitallium was zero, yet a vigorous reaction occurred. From other potential measurements it can be deduced that the difference between copper and titanium is not

over 20 millivolts and would not be enough to account for the extensive reaction of the right femur of cat 4.

Another example of an unfavorable reaction with low potentials is seen in the case of nickel implants of cat 3, Figure 5. The potential difference between nickel and chromium on the right side was 20 millivolts, whereas on the left

Figs 1 to 6 Roentgenographic positive prints of cat femurs cleaned and photographed after a postoperative survival period of 186 to 329 days. Side and end views of

*This implant had sloughed out of the bone and was encapsulated in the adjacent soft tissue

the metallic implants are shown in the right and left femur. The proximal end of the bones is at the top of the figures, and the metals used are listed from proximal to distal.

†Beryllium (atomic weight 9.02) is more transparent to x rays than is bone. Both of these implants are *in situ*.

between nickel and cobalt it was 130. The reaction is essentially the same on both sides and is characterized by a marked erosion without cortical proliferation. Chromium has remained inert on the right while cobalt has caused some erosion on the left.

An example of moderate potential difference between lead and titanium with little reaction is seen in the right femur of cat 12 with an electromotive force of 260 millivolts. There is evidence of only a slight cortical reaction with bone grown over about half of the exposed surface of the lead im-

plant. On the left side of the same cat the difference between titanium and a gold-platinum alloy was zero and there is practically no bone reaction, but the alloy pin remained loose as if the bone were voiding it. This is in contrast with the growing into contact with the lead.

Another instructive example of the lack of direct correlation between potential and reaction comes from the comparison of the reactions of manganese and cadmium. When either of these was implanted adjacent to a nonreactive pin of vitalium, stainless steel, or titanium, a high potential difference resulted. Couples containing manganese gave vigorous reactions but those con-

TABLE II.—POTENTIALS AND TYPES OF REACTION OF BONE TO METALS

A copper electrode as adjacent muscle as used arbitrarily as zero point of reference because most of the couples in the bone contained one implant which gave very low potential with copper. Reactions are classified according to gross appearance and ray photographs.

taining cadmium gave very mild ones (cats 3, 6, 8, 9, and 10), and the reactions are centered around the reactive metal and not around the pair forming the electrolytic couple. Beryllium couples with high potentials (cats 15 and 16) show even less reaction than those containing cadmium.

In one instance (cat 6) manganese implants became completely intramedullary and the cortex healed over them. The titanium pin on the right side remained in place. One may imagine that the formation of insoluble manganese soaps from fat in marrow cavity on surface of the pins tended to inactivate them and permitted healing of cortex.

The activity of manganese was greatly reduced when alloyed with chromium (manganese 70 chromium, 30 parts) but the potential between the alloy and a copper electrode in adjacent muscle was similar to the unalloyed manganese. A manganese titanium alloy (manganese 65 titanium 35 parts), on the other hand reacted similarly to unalloyed manganese. This illustrates the well known property of chromium to suppress corrosion of metals with which it is alloyed.

The present study together with the observations made on the preceding series, throws some light on the behavior of bone toward metals as determined by their solubility. Evaluation of every metal individually is necessary; for example magnesium is very soluble but not particularly toxic while copper is much less soluble but highly toxic. Chromium would be very toxic if it were soluble, since chromium salts are very toxic to all living tissues, but the metal caused no reaction. Beryllium caused little reaction presumably by reason of its insolubility but beryllium salts are known to cause bone lesions similar to rickets when taken by mouth. Lead shows no toxicity is judged by the tendency of the cortex to cover it, yet lead salts are toxic.

Tantalum is not used in this series, but the report of Burke indicates that this metal is quite inert in both bone and soft tissues and has ideal physical properties. The fact that tungsten was inert in our experiments and that it is closely related to tantalum in the atomic series of the elements is of some academic interest.

PRACTICAL CONSIDERATIONS

The possibility of using powdered, sterilized metallic manganese to stimulate callus formation in

nonunion of fractures is suggested by the way bone reacts to this metal. It appears to be largely inactivated in the medullary fat, as shown by the femurs in which it became intramedullary and the cortex healed over it with scarcely a trace of the original holes. The powdered or finely granulated metal might be sprinkled on the exposed nonunited ends of a bone during an open operation, or it is conceivable that it could be injected without an operation in a suspension of an absorbable medium.

Differences of electrical potentials in themselves do not cause unfavorable bone reaction; hence it seems reasonable to conclude that any alloy which might be made of metals with which bone reacted favorably individually would be tolerated well in an alloy. This postulate should be of value to the metallurgist interested in the manufacture of prosthetic materials.

SUMMARY AND CONCLUSIONS

Two implants of dissimilar metals were paired in such a way that varying degrees of electrical potential were obtained, and allowed to remain 6 to 11 months in femurs of cats. Bone reactions were not closely correlated with the magnitude of potential differences, but remained characteristic for a given metal or alloy. Electrolysis is not the primary cause of unfavorable bone reactions. The primary causes are determined by physical and chemical properties of the metal itself. Solubility and the degree of toxicity of the dissolution products appear to be the chief factors. If electrical potentials play no part in inciting reaction it seems safe to assume that the unfavorable reactions seen in alloys are due to the presence of toxic metals (such as nickel, copper, or manganese) in them. Alloys which consist of nontoxic metals should be nontoxic regardless of potential differences of their components. Theoretically, vitallium comes nearer to meeting this requirement than stainless steel, but tantalum may prove to be the metal of choice when sufficient data on it have been accumulated.

THE MANAGEMENT OF ACUTE EMBOLIC OCCLUSION OF THE ARTERIES TO THE EXTREMITIES

LAWRENCE N. ATLAS, M.D. Cleveland, Ohio

WHEN an artery in an extremity becomes acutely obstructed by an embolus, a two-fold therapeutic problem presents itself. The first is in the nature of an emergency. It is the necessity of immediately restoring sufficient circulation to preserve the viability of the limb. The second is predicated on the successful accomplishment of the first. It is to promote therapeutically the growth of a collateral circulation so that the functional capacity of the limb as well as its viability will be preserved. Both are accomplished by increasing the volume rate of blood flow through the available collateral circulation.

For practical therapeutic purposes, any method designed to augment the quantity of blood flowing through a collateral arterial network must exert its effect by diminishing the peripheral resistance to blood flow through a dilatation of the arteriolar capillary bed into which the collateral vessels ultimately empty. Since ischemic tissue is saturated with vasodilating substances, it should be expected that such an increase in the flow of blood through collateral channels would automatically follow the acute occlusion of a principal artery. As a matter of fact, cases of acute embolic occlusion are not infrequently seen which open and develop an effective collateral circulation without any therapeutic assistance. Many more would respond in a similar manner were it not for the fact that when an embolus suddenly occludes a peripheral artery the arterial bed in that extremity and sometimes in the opposite extremity as well is thrown to a greater or lesser degree of spasm. I have seen instances in which a minute embolus lodged in the periphery of a leg has given rise to bilateral vasospasm of such magnitude that an organic occlusion of the bifurcation of the abdominal aorta was simulated. A case in point follows:

A K. white female aged 37 years, came under observation December 9, 1940. For years she had suffered from rheumatic carditis with fibrillation for many years, but as she controlled. While convalescing from an elbow operation, she suddenly experienced an acute severe pain in her right leg and foot accompanied by sensations of coldness and numbness.

From The Peripheral Vascular Clinics, Cleveland City and Mount Sinai Hospitals, and from The Department of Surgery School of Medicine, Western Reserve University.

About 30 minutes later similar symptoms appeared in the right foot and leg.

The patient appeared to be acutely ill and in considerable distress. Her pulse as grossly irregular. Both lower extremities distal to the knees were very cold to the touch. The right foot was markedly cyanotic. Both feet exhibited as like pallor on elevation. No pulsation was palpable in either femoral, popliteal, posterior tibial, or dorsalis pedis arteries. The entire picture resembled that of block in the region of the bifurcation of the abdominal aorta. However the possibility of minor embolus with major degree of reflex vasospasm could not be readily ruled out, and, in view of her poor general condition, it was decided to employ conservative therapy. Within 7 hours, normal arterial pulsation had returned throughout the entire right lower extremity and within 24 hours, excellent pulsation was palpable in the left femoral and popliteal arteries. At this time both feet were warm and of normal color. Symptoms had disappeared. Figure presents series of oscillometric tracings illustrating this remarkable degree of bilateral reflex vasospasm resulting from minor embolic occlusion of an artery in the distal portion of single extremity. Patient made an excellent recovery only to experience several months later from cerebral embolus.

The vasospasm just described has important implications concerning treatment. As has been demonstrated, an embolus lodged in the distal portion of an extremity may reflexly render the more proximal and larger arteries pulseless. Unless the possibility of spasm is considered, these larger spastic vessels may be surgically explored for the purpose of removing what is erroneously considered to be the offending embolus.

A white female aged 26 years, came under observation April 8, 1940. She had suffered from rheumatic carditis with fibrillation for many years, but as she controlled. While convalescing from an elbow operation, she suddenly experienced an acute severe pain in her right leg and foot accompanied by sensations of coldness and numbness.

The right foot and lower leg were mottled, very cold to the touch, and exhibited as-like pallor on elevation. Excellent pulsation as palpable in the right femoral artery, no pulsation was palpable in the popliteal artery or its branches. Oscillometric readings at the level of the popliteal space were zero. A diagnosis of an embolic occlusion of the right popliteal artery was made. Under local anesthesia, the popliteal artery was exposed. It was markedly constricted, its diameter measuring only 1/16 of an inch. The constricted vessel exhibited extremely faint pulsation and contained no thrombus. No attempt was made to explore the artery. The wound was closed and conservative therapy was instituted. Within 24 hours, the foot was pink and warm and symptoms had subsided. She made an excellent anatomical and functional recovery and has remained well.

Another important bearing on treatment concerns the use of heat. It has been demonstrated (1, 2, 5) that external heat stimulates the metabolic activity of ischemic tissue and hastens the onset of gangrene. Therefore, when the collateral circulation in an extremity rendered acutely ischemic is so spastic it cannot relax in response to the huge concentration of vasodilating substances surrounding it, the use of heat as an additional dilating stimulus is, under the circumstances not only illogical but dangerous.

During the acute stage of an embolic occlusion, therapy should concern itself with relaxing spastic vessels and preventing their thrombosis. To secure the desired relaxation, intravenous injections of papaverine hydrochloride in $\frac{1}{2}$ grain doses every 4 hours for 48 hours and then 3 times a day for a week are almost specific (4). To prevent thrombosis of the collateral circulation pending its dilatation, and to prevent spreading thrombus formation starting at the site of the actual organic occlusion, heparin is administered (3, 6, 7, 8, 9, 10). Since many of these patients are cardiacs, heparin can rarely be administered in a continuous intravenous infusion of saline as is the usual procedure. Instead, it must be given intravenously in 4 hour doses of 50 milligrams each. This dosage may have to be adjusted to keep the blood clotting time at a minimum level of 15 minutes.

The limb is swathed in cotton and protected with an unlighted cradle. After spasm has disappeared, as indicated by an increase in the surface temperature of the foot, an improvement in its color, and subsidence of symptoms, measures may be instituted for the purpose of further stimulating the flow of blood through collateral channels. Mild local heat, the rhythmic venous occlusion machine, and the suction-pressure boot may now be safely employed.

Should the ischemia fail to improve or become progressively severe despite the administration of papaverine and heparin, an actual organic block of a major vessel must be considered and an embolectomy with the patient still heparinized performed.

Individuals who have sustained an embolic occlusion may present themselves for treatment several weeks after the acute vascular accident has occurred. In such instances, it is often found that a periarthritis involving the thrombosed vessel is stimulating afferent sympathetic neurones with resultant pain or reflex spasm of the collateral bed. Resection of the offending thrombosed arterial segment is indicated. The following cases are illustrative.

Fig 1. A series of tracings taken with a recording oscillogram depicting the remarkable degree of bilateral vaso-spasm which may result from an embolic occlusion of an artery in the distal portion of a single extremity. Tracing taken December 1, 1940, 1 hour following embolic occlusion of artery in distal portion of left leg, reveals absence of pulsation in each popliteal space. Tracing taken December 4, 1940, 72 hours following acute vascular accident, reveals excellent pulsation in right popliteal space and slight pulsation in left popliteal space. Tracing taken December 15, 1940, 2 weeks following occlusion, reveals excellent and equal pulsation in each popliteal space. Conservative treatment employed throughout. Note irregularity in magnitude and spacing of pulsation due to auricular fibrillation.

M. B., a white male aged 48 years, came under observation March 27, 1939. He had suffered from rheumatic heart disease for many years and was subject to bouts of fibrillation. About 10 days before I saw him, he experienced sudden severe pain in both feet accompanied by sensations of coldness and numbness. Since then, he had been incapacitated by a peculiar type of pain referred to the calves of his legs. The pain was present constantly and was worse at night. He described the pain as squeezing as if the calves of his legs were caught in a closing vise. The pain was so severe that morphine gave only transient relief. He also suffered from pain, coldness and numbness of the feet but to a lesser degree.

Both feet were cold to the touch, somewhat cyanotic, and exhibited pallor on elevation. There was no tissue necrosis. Excellent pulsation could be felt in each common femoral artery down to its bifurcation. No pulsation could be detected either manually or with the oscillogram distal

Fig. 1. Left. Low power magnification of microscopic section of segment of thrombosed superficial femoral artery and adherent femoral vein resected weeks after acute embolic occlusion. Sections show striking changes in femoral artery and complete occlusion of lumen by thrombus mass composed in great part of red blood cells and fibrin. The intima in places is thickened and shows degenerative changes. The media likewise shows degenerative changes. The ad. endothelium and regional tissues show moderate to considerable round cell infiltration and some edema. The veins in the section show some thickening of the walls and some round cell infiltration and edema of the outer coats and regional tissues. A small nerve in this section shows some edema and round cell infiltration especially perineural. Diagnosis: Femoral artery occluded by recent thrombus.

Fig. 2. Right. Low power magnification of microscopic section of thrombosed brachial artery resected weeks after acute embolic occlusion. Section shows the wall of the artery to be somewhat thickened. Most of the thickening is due to reaction in the serosa. The lumen is filled with blood that has undergone considerable autolysis. Intermingled with the blood are fibrin strands. There is moderate amount of fibroblastic activity between the clot and the vessel wall. The ad. endothelial coat is considerably thickened and there is noted fibroblastic activity. There is also present moderate amount of regional round cell infiltration. Diagnosis: Organizing embolus of brachial artery with subsequent periarthritis.

to these points. The calf muscles are relaxed and flabby. The symptoms in the feet are interpreted as being of ischemic origin. Like the pain, the calves suggested stimulation of intravascular and perivascular sympathetic nerve fibres. Accordingly under local infiltration anesthesia, the proximal portion of each superficial femoral artery as exposed for the purpose of performing an adventitial stripping. However this proved to be impossible because of inflammatory adhesions between the thrombosed arteries and the adjacent femoral veins. The arteries are opened and the thrombi found to be adherent. A small section of each thrombosed artery and adherent vein as excised (Fig. 1). The operation gave immediate and complete relief of the pain in the calf as of his legs. Subsequently measures are instituted to stimulate the growth of collateral circulation. He recovered complete use of his extremities and has been well since.

P. D., 41 yr. male, aged 41 years, came under observation February 2, 1941. About weeks before admission he experienced sudden severe pain in the antecubital space of his right arm. The pain rapidly spread up the inner aspect of his right arm, and the hand became cold and numb and began to ache. The pain, coldness, and numbness in hand became increasingly severe, the end of the thumb and forefinger became black, and finally more the fingers was lost.

Medical consultation revealed the presence of an aortic valvulitis with questionable congenital heart disease. X-ray as negative for cervical ribs. The right hand, as for cold, anesthetic, cyanotic, and anesthetic as like pulse on elevation. Cutaneous sensibility as absent, and the patient was unable to move his fingers. The distal phalanges of the first and second fingers are gangrenous. The radial and ulnar arteries are pulseless. Oscillometric readings at the level of the right forearm are zero. The entire length of the brachial artery from its junction with the axillary down to its bifurcation as palpable as pulseless tender cord like structure. It is felt that this thrombosed vessel as given rise to reflex spasm of the collateral circulation to the hand. Accordingly under general anesthesia, the entire length of the brachial artery as exposed. It is completely thrombosed. The artery as opened, and the thrombus was found to be adherent. Feeble pulsation as present in the terminal portion of the axillary artery. The thrombosed brachial artery as severed at its junction with the feebly pulsating axillary. Within minutes, the distal stump of the axillary artery dilated and began to pulsate vigorously. The entire length of the thrombosed brachial artery as excised (Fig. 2). Twenty-eight hours later the patient as able to move his fingers, sensibility had returned, the hand as pink and warm, and symptoms had

disappeared About 3 weeks after operation, he suffered a right cerebral embolus with complete left hemiplegia He survived this episode and is still living The hemiplegia has remained Fortunately, adequate function has been restored to the right hand, thus sparing the boy from total incapacitation

GASTROSTOMY—JEJUNAL INTUBATION

J DEWEY BISGARD, M D, Omaha, Nebraska

GASTRIC surgery is still attended by primary mortality and morbidity which is not commensurate with the magnitude of the operations Hospital mortality rates vary from 10 to 20 per cent as shown in recent reports from representative clinics From the evidence which is constantly accumulating, it is becoming more and more apparent that much of this excessive mortality is the result of malnutrition which is present to a minor degree in all and to a severe degree in many of the patients subjected to gastric operations Only recently has there developed an appreciation of the extent of this depletion of such vital nutritional elements as plasma proteins and vitamins and the far reaching influence of these deficiencies upon the repair of tissues, upon gastric and intestinal motility, and upon the distribution of fluids

In autopsy reports many of the deaths are attributed to the pathological findings which are immediately apparent but which in reality are often secondary to nutritional deficiencies For example, when a patient who has depleted his food stores by starvation resulting from pyloric obstruction dies following operation, the autopsy may reveal such obvious causes of death as pulmonary edema, or as peritonitis resulting from leakage from the line of suture In all probability, however, the edema resulted from hypoproteinemia or the leakage from the failure of tissue repair caused by protein, vitamin C, and possibly other unknown deficiencies

In most of these malnourished patients it is impossible to replenish their depleted food stores before operation is undertaken and one can at best provide only a very temporary supply of certain essential elements To this end, however,

all available facilities for rehabilitation, such as the liberal administration of water, sugar, whole blood, blood plasma and vitamins, should be utilized Since the nutritional demands are tremendously increased following operation and since the parenteral route meets these demands so inadequately, it is very important to provide nourishment as soon as possible by alimentation This can be done starting immediately following operation by means of oral jejunal feedings Following Ravdin's report approximately 3 years ago, the method with technical variations has been used by me almost routinely In the earlier cases two Levine tubes were threaded into the stomach, one through each nostril before the operation was started At the completion of the gastrojejunal anastomosis one of these tubes was threaded through the stoma into the distal loop of the jejunum for a distance of 8 to 12 inches Through this tube feedings were administered every hour, starting as soon as the patient returned from the operating room Each feeding consists of 2 to 4 ounces of peptonized skimmed milk containing 5 grams of glucose to each 100 cubic centimeters of the mixture, followed in some instances by 1 or 2 ounces of normal salt solution, as indicated, to maintain fluid balance By this means alone the patient receives from 2800 cubic centimeters of fluids to as large quantities as desired in addition to the normal salt requirements, so that it is unnecessary to administer fluids parenterally In addition these feedings provide in 24 hours 150 grams of glucose, an equal quantity of milk sugar, 95 grams of the much needed protein, and the minimal caloric requirement of 1,795 calories To these feedings there has been added the vitamins B-complex and C in the quantities indicated, and other medications as desired Because 2 patients pulled

Fig. Oral jejunal intubation for feeding. Three days after an anterior Polya resection showing the two Levine tubes which were threaded into the stomach (one through each nostril) before operation. At operation one tube was threaded through the stoma, *S*, into the distal loop of the jejunum, the other one was left in the gastric stump in order to keep it empty by constant suction. The area of increased density between *O* and *S* represents the thick edematous walls of the stomach and jejunum around the stoma.

Fig. Gastrostomy jejunal intubation for feeding. Roentgenograms taken 7 days after gastroenterostomy to relieve pyloric obstruction due to postcholecystectomy cicatrization about the duodenum. The tube enters the abdomen at *A*, the stomach at *B*, and the jejunum through the stoma at *S*. Note the area of decreased density outlining the enormously dilated stomach. A small amount of barium taken by mouth outlines the cardia. Incidentally shadowed are the two right renal calyces shown.

out the Levine tubes unintentionally during sleep the original procedure has been modified in the malnourished patients as shown in the roentgenogram, Figure

After the gastrojejunal anastomosis is completed a catheter gastrostomy is done and the tip of a catheter is threaded through the stoma into the distal segment of the jejunum. The wall of the stomach at the site of gastrostomy is anchored to the abdominal wall and the proximal end of the catheter is brought out through a stab wound to the left of the incision. It has been learned that the catheter can be passed most simply through the stoma into the jejunum by grasping the tip of the catheter in a curved hemostat with which it is directed through the small gastrostomy incision into the jejunum. Through this catheter feedings are administered as has previously been described.

If the jejunum is distended rapidly some discomfort may be produced. Therefore the feedings are administered slowly drop by drop from a

gravity bottle. The stomach is kept empty by constant suction applied through the Levine tube in the stomach.

Two ounces of water are given by mouth every hour. This serves two purposes. It pleases the patient and, as it returns through the Levine tube, it washes the stomach and the tube. On the third day suction is discontinued, but the tube is left in place so that suction can be resumed in case of distress or other evidence that the stomach has failed to empty. On the fourth day hourly feedings of 4 ounces of milk and cream in addition to water are given by mouth and the jejunal feedings are reduced to 2 ounces. On the 5th day a 6 meal bland gastric diet is started and jejunal feedings are discontinued. If oral feeding progresses satisfactorily the gastrostomy catheter is removed on the 7th or 8th day.

This method of intubating the jejunum has certain advantages over jejunostomy. It does not fix the jejunum to the abdominal wall or cause other adhesions about it that act as potential sources of

Fig 3 Gastrostomy jejunal intubation supplementing gastric resection.

jejunal obstruction and there is less likelihood of leakage

In our small series of cases no complications or ill effects have been encountered. To the contrary, convalescence in each case has been extraordinarily uneventful.

It is obvious that in cases with small residual gastric pouches which retract up under the costal margin, the procedure is technically impossible. In these cases recourse is had to oral jejunal feedings through the Levine tube which had been passed into the stomach before operation. Fortunately, however, little difficulty has been encountered in the severely malnourished patients who are most in need of immediate feeding because they are thin and lax from much loss of

Fig 4 Gastrostomy-jejunal intubation for preliminary jejunal feeding of patients with gastrojejuno-colic fistula. The tube by-passes the jejunal-colic fistula and delivers food and water where it will be assimilated. After adequate restoration of nutrition the radical corrective operation can be done with much less risk.

weight and their stomachs are usually large as a result of obstruction.

Recently, jejunal feedings by means of gastrostomy-jejunal intubation have been used to rehabilitate a severely depleted patient with a gastrojejuno-colic fistula. A diagram of the procedure is shown in Figure 2. The rapidity of both physical and biochemical restoration was impressive as was the convalescence from the corrective operation which was done 12 days later. Following this corrective operation which included partial resection of the stomach, the gastrostomy tube was threaded into the jejunum through the new stoma and the jejunal feedings were continued.

MULTIPLE MYELOMA

RALPH A. GHORMLEY, M.D. F.A.C.S. GEORGE A. POLLOCK, M.B. F.R.C.S. (Ed.) F.A.C.S.
BYRON E. HALL, M.D. and LAWRENCE H. BEIZER, M.D. Rochester, Minnesota

IN a previous communication two of us (Ghormley and Pollock) reviewed the clinical and laboratory findings in 86 cases of multiple myeloma encountered at the Mayo Clinic between January 1, 1924, and December 31, 1936. This present study was undertaken in an endeavor to bring the statistical survey of this disease up to date. Forty-one additional patients who had multiple myeloma were examined in the last 3 years, making a total of 127 patients examined and treated in the 16 years from January 1, 1924, to December 31, 1939. It is of interest to note the increase in the number of cases in which a diagnosis of multiple myeloma has been made since our paper on this subject was published.

Multiple myeloma is a highly malignant tumor of the bone marrow which tends to occur after the fifth decade of life. Although the disease generally is insidious in its onset, on occasion it may run a fulminating course. In one of our cases only 4 months elapsed from the appearance of the first symptom until the death of the patient.

The etiology is unknown. Men are affected about twice as frequently as women. Trauma does not appear to influence the onset of the disease although in several cases history of injury was elicited on inquiry. Its importance as an etiological factor was not emphasized by the patients. The original description made by Dalrymple in 1846 of the pathological findings cannot be improved. Speaking of the appearance of two vertebrae and a rib at necropsy he said "the disease appears to have commenced in the cancellated structure of the bone for the external osseous laminae are firmer and more healthy than the internal. . . and again, "the smoother surface of the rib however is raised by internal growths elevating the outer laminae here and there into irregularly sized and rounded dark red projections visible through the periosteal covering. The outer layers are steel hard requiring the exertion of some force to cut them; they are thin, however and, when sliced, expose large cancellous cavities filled by a red gelatiniform substance threaded here and there by fine bony fibers. It is in these fibers of still-existing bone that many of the more important morbid changes may be witnessed.

From the Section on Orthopedic Surgery and the Division of Medicine, May Clinic

Microscopically the tumors are made up predominantly of cells which closely resemble plasma cells. They possess the same tinctorial characteristics, which can be brought out by the Unna-Pappenheim stain. However the nucleoli in these cells are more prominent than those in normal plasma cells. If a tumor nodule is the source of the material examined the histological appearance is uniform and comprised almost entirely of these cells. The myeloid tissue and fat spaces seen in normal marrow are not encountered. On the other hand, if a portion of marrow between tumor nodules is examined, the picture may be essentially normal except for the finding of isolated tumor cells or small nests of tumor cells.

Imprint preparations made from bone marrow obtained at biopsy or smears made from aspirated material, stained with any one of the Romanowsky combinations of stains, lend a somewhat different appearance to these cells. They vary in size from 7 to 30 microns and have a definite outline. They are usually oval but occasionally are somewhat irregular. The cytoplasm ordinarily is deeply basophilic and has a lighter staining zone adjacent to the nucleus. The nucleus is round or oval and has a variable type of nuclear structure, the chief characteristic of which is a large, conspicuous, sharply demarcated nucleolus. The chromatin usually is arranged either in fine or coarse strands, rarely in dense masses, and is sharply differentiated from the parachromatin. The identity of tumor cells in myeloma has not been established. Inasmuch as they differ from normal plasma cells and have a characteristic appearance morphologically, they are now usually referred to as "myeloma cells."

The progenitor of the myeloma cell is unknown. Many theories have been advanced and the cells which have been suggested as possible sources of these elements are as follows: myeloblasts, dysplastic hemocytoblasts, the reticuloendothelial cells, lymphocytes, megakaryoblasts and osteoblasts. From evidence in recent literature and in our material, it seems likely that in most instances the myeloma cell is derived from reticuloendothelium.

SYMPTOMS

The symptoms are diverse and, frequently apparently unrelated. There are no symptoms

which are pathognomonic of the disease. Of our entire series of 127 cases, only 32 were proved at pathological examination. Eighty-three of the patients were males and 44 were females. The oldest male was 75 years of age, the youngest 4 years. The average age of the patients at onset of symptoms was 54 years. The duration of symptoms at the time of the first examination at the clinic ranged from 3 weeks to 5 years. The average duration of symptoms was 1 year. The longest duration of the disease was 9 years, the shortest 4 months. Pathological fractures were present in 13 proved cases, 40.6 per cent.

Backache, by far the most common symptom, was the major complaint in most of our cases. When this was the sole symptom, the reason for the erroneous diagnosis of arthritis of the spinal column or neuritis is understood. Loss of strength and progressive weakness were the second most common cause for the patient's seeking advice. Anemia, loss of weight, or occurrence of a pathological fracture was described less frequently, and the presence of a palpable tumor was rare.

In about 70 per cent of our cases, albuminuria was present, although in only 36.5 per cent of cases in our second series was renal damage present, as evidenced by casts, hematuria, and an elevated value for blood urea. It is possible for a condition which has been diagnosed and treated as nephritis ultimately to be proved multiple myeloma. In one of our cases, excessive albuminuria of long standing was the only finding, on further investigation, Bence-Jones proteinuria was discovered. Results of sternal puncture, advised because of this finding, revealed the true nature of the disease as multiple myeloma. Investigation for Bence-Jones bodies was made in 112 of the 127 cases, with positive findings in 68, 60.7 per cent. A similar research in the proved group of cases of multiple myeloma gave positive findings in only 12 of the 29, 41.3 per cent. The more important of the various investigations carried out are listed in Table I.

DIAGNOSIS

Although symptoms are not pathognomonic of this disease, the discovery at examination of several of the findings listed in Table I should suggest the possible diagnosis of multiple myeloma.

Biopsy or sternal aspiration to confirm the diagnosis of multiple myeloma is warranted in cases in which the patient is a man more than 50 years of age who has changes in bones and progressively severe backache associated with Bence-Jones proteinuria or high level of protein in the serum. Multiple, punched-out areas of de-

TABLE I — SUMMARY OF DATA CONCERNING CONSTITUENTS OF BLOOD IN ENTIRE SERIES

Investigation	Estimations*	Abnormal results		
		Type	Cases	Per cent
Albumin-globulin ratio	23	Reversed	13	56.5

Blood creatinine	9	Elevated	5	55.5
Bence-Jones protein in urine	112	Positive	68	60.7

*One estimation listed per case

struction in the skull, ribs, and spinal column usually are accepted as roentgenological evidence of multiple myeloma, but it must be recognized that widespread metastatic carcinoma may give rise to similar appearances. In this connection, it is well to remember that the presence of myeloid immaturity and a "greasy" appearance in the blood smears described as suggestive of multiple myeloma are found in metastatic malignant disease which involves the bone marrow and also in paroxysmal hemoglobinuria. Magnus-Levy admitted the possibility of Bence-Jones proteinuria resulting from activity of normal marrow.

The condition of the patient is not always an index of the extent of the disease. We have been astonished to observe patients in comparatively good condition who had extensive skeletal destruction and again, we have been embarrassed at our inability to discover a definite skeletal focus on examination of a patient who is dying and has all other clinical signs and evidences of multiple myeloma. With so many possibilities for error, accurate diagnosis is difficult. The diagnostic results of biopsy are excellent, but many patients are reluctant to undergo a surgical procedure which is not calculated to give relief.

The comparatively recent introduction of sternal aspiration has placed at our disposal a procedure which will permit accurate diagnosis in most cases. The method is so simple in application that its routine use in suspected cases should be possible. Material is aspirated from the marrow cavity of the sternum by means of a dry syringe

and is placed in a 2 cubic centimeter paraffin lined test tube containing a small amount of heparin. Material is mixed well to prevent clotting. Smears are made from this material which are stained with Wright's stain and then by Giemsa's. The presence of myeloma cells is diagnostic of the condition but their absence does not rule it out.

PROGNOSIS

Prognosis is uniformly poor in all cases in which evidence of involvement of bone is present. In our entire series, the average duration of life after diagnosis had been made was a year which conforms fairly accurately to the figure of 14.03 months which we gave originally in our proved series. The longest duration of the disease in our proved group of cases was 9 years and 2 months, and the shortest, 4 months.

In cases in which multiple myeloma affects the soft tissues only it is possible that complete extirpation of the lesion will result in cure.

Other therapeutic measures are foredoomed to failure, yet there is evidence from the follow up reports of our patients that temporary relief and improvement have followed the use of roentgen therapy and general tonic measures. At this time the authors are unable to state whether the patients' lives have been prolonged materially by the use of these measures.

THE SURGICAL ANATOMY OF THE SUPERIOR HYPOGASTRIC PLEXUS

With a Report of 150 Personal Dissections

B BERNARD WEINSTEIN, M S , M D , New Orleans, Louisiana

SINCE its existence was first noted by von Haller many anatomists and surgeons have studied and given varied names and descriptions to that collection of sympathetic fibers which only of late is being designated properly as the "superior hypogastric plexus." This plexus, which is rarely a single nerve and is always prelumbar, is commonly and erroneously referred to by the misleading term, "the presacral nerve" (Latarjet and Bonnet). Recently Davis (23-26), Labate (38) and others have stressed the inaccuracy of the term "presacral" and have come to popularize the more acceptable terminology of Sappey, "superior hypogastric plexus."

In 1925 Cotte introduced the operation of resection of the superior hypogastric plexus for the relief of pelvic neuralgia, vaginismus, dysmenorrhea, hypoplasia of the uterus, metrorrhagia and sexual neurosis (2-3). Subsequently the procedure was popularized and the indications for its use extended by numerous contributions, particularly those of Cotte (5-20) and of Leriche (44-46). The successful and widespread use of extirpation of the superior hypogastric plexus led to its adoption for the relief of pain arising from such varied pathological conditions as (a) inoperable carcinoma of the pelvic viscera, (b) intractable primary dysmenorrhea, (c) cord bladder, (d) intractable cystalgia, (e) spasm of the bladder neck, (f) obstipation of rectal origin, (g) Hirschsprung's disease, (h) pruritus vulvae, (i) vaginismus, (j) dyspareunia, (k) sclerocystic degeneration of the ovaries, (l) kraurosis vulvae, (m) severe persistent postoperative pelvic pain, and pelvic and abdominal pain of obscure origin.

The increase in indications for extirpation of the superior hypogastric plexus and the wide adoption of the procedure as reflected by the numerous reports in recent literature created the need for, and gave a marked stimulus to, the study of the available literature on the detailed anatomy and surgical anatomy of the plexus. This was found to contain many conflicting reports. In fact, after

noting the repetition of inaccuracies contained in the older literature one is tempted to agree with Byron Robinson when he states "It would astonish any student to know how little has been published in regard to the nervous system of the female genitals that is of an original character."

The existence, in the literature, of this wide variety of descriptions of the plexus led to a series of careful studies by a number of recent investigators, but as Davis (23-26) has so well stated, "Painstaking and exhaustive though this work has been, and possibly because of these factors the variations in the findings of different writers on the morphology of the plexus are even wider than those exhibited by the older authors."

While all types of plexus patterns have been reported, the main conflict lies between those who have reported the predominance or sole existence of "presacral nerves" and those who have substantiated the finding of a predominance of "superior hypogastric plexuses." An understanding of the development of these differences can be derived from an appreciation of the fact that single nerves, bilateral cords, and a multiple variety of plexus formations occur, and when an investigator has had occasion to report a short series of dissections in which a single type predominates there is apt to be an emphasis on that type, whereas the result of a larger series would at once demonstrate that all varieties reported may occur, and that the plexus patterns predominate. It is also true that superficial and inadequate dissection will frequently reveal a single nerve or bilateral cord, whereas further careful dissection of the same subject will reveal many intercommunicating twigs and may uncover a typical plexus arrangement. It is hoped that this investigation, containing as it does the largest group of detailed dissections thus far reported, will tend to crystallize more clearly our concept of the morphology of the superior hypogastric plexus.

MATERIAL AND METHODS OF STUDY

The specimens included in this study were obtained from the routine cadaveric material in the department of gross anatomy, Tulane Univer-

From the Departments of Gross Anatomy and Gynecology
Tulane University, School of Medicine.

sity during the summer sessions 1938 and 1939 and the regular sessions 1938-1939 and 1939-1940, which were made available by Dr. Wilbur C. Smith and also several autopsy specimens from Toussaint Infirmary, New Orleans, were provided through the courtesy of Dr. John A. Lanford. While 10 dissections were done on infants in order to determine whether there are differences in the morphology of the plexus in the infant and the adult, as claimed by some investigators, none was found and the infant material is not included in this report. This report considers the findings in 150 adult dissections, representing 90 females and 130 males. Of the 90 females 14 were negro and 6 white, while 96 of the male specimens were negro and 34 white. This preponderance of the negro material is in accord with the usual percentage distribution in the anatomical material obtained by this laboratory and though there are many interesting studies on anatomical and surgical peculiarities in the negro, particularly those of Matas, Souchon and Hoffman, there appeared to be no differences in the morphology of the superior hypogastric plexus in the two races and therefore for statistical purposes the group will be considered as a whole throughout the following discussion.

Detailed dissections of the entire abdominal and pelvic sympathetic system were made on the first 33 cadavers. This included a study of the celiac plexus, the aortic plexus, the ovarian and renal plexuses, the lumbar sympathetic trunks, and the superior hypogastric plexus. The connections of the superior hypogastric plexus, including all of its afferent and efferent fibers, with the ganglionated sympathetic trunk and the sympathetic ganglia proper were studied. The fibers were traced from their origins to their final distribution in the pelvic viscera. In the remaining subjects the detailed gross anatomy of the superior hypogastric plexus and the interiliac trigone was recorded with notations on the occurrence of anomalous structures in the interiliac trigone. In every instance a record was made of the size of the interiliac trigone and a sketch made of the morphology of the plexus and the relationships existing between the plexus and the contents of the interiliac trigone. In addition, observations were made on the variations of the sigmoid mesocolon. The female subjects, in every instance, were submitted to detailed study.

CONNECTIONS OF THE SUPERIOR HYPOGASTRIC PLEXUS

The superior hypogastric plexus is a direct downward continuation of the intermesenteric

nerves of Petit Dutaillis-Flandrin. By way of these nerves it is connected above with the celiac plexus and the lumbar sympathetic ganglia (upper or 3). The intermesenteric nerves are composed of several (2 to 6) parallel fibers on either side of the aorta. These parallel fibers are connected by innumerable fibers and form the lateromesenteric or aortic plexus. The intermesenteric nerves arise from the renal or aorticorenal ganglion, the periaortic plexus of the renal artery and the transverse aortic bar and the first and second lumbar sympathetic ganglia. They at first lie on the lateral aspect of the aorta, the right being somewhat further lateral than the left, which is closely adherent to the lateral aspect of the aorta. They then pass downward and medially to the anterior surface of the aorta, on which they continue downward (receiving and distributing fibers to the inferior mesenteric ganglion and plexus) to the bifurcation of the abdominal aorta at which level they enter the interiliac trigone and terminate by forming the superior hypogastric plexus. Just prior to their termination they receive fibers from the lower lumbar ganglia.

The plexus is connected above with the inferior mesenteric periaortic plexus, and when present the inferior mesenteric ganglion. These fibers may run downward to join the plexus directly or may join the intermesenteric nerves.

The superior hypogastric plexus receives fine branches from each of the lumbar sympathetic ganglia. The contribution of the superior (first and second) ganglia is usually the more marked, frequently consisting of several distinct fibers which are contributed to the plexus via the lateromesenteric nerves. The fibers from the inferior ganglia are inconstant and of finer caliber and when present are of a lesser number than the superior. The branches from the inferior lumbar ganglia occasionally join the intermesenteric nerves but more frequently enter directly into the superior hypogastric plexus, being found inferior to the termination of the intermesenteric nerves in the superior hypogastric plexus. The number of ganglia in the lumbar section of the cord varies, hence the terms superior and inferior ganglia are used in preference to numerical designations. However in every case fibers are contributed to the plexus by all the lumbar sympathetic ganglia. The preponderance of fibers from the upper lumbar ganglia is in keeping with the observations of Hovelacque, Delmas and Lacroix, Davis, Labate, and others.

In addition to these twigs from the lumbar sympathetic ganglia, fine fibers running from the sympathetic trunk proper to the superior hypo-

gastric plexus were demonstrable in 3 instances. The rarity of these fibers is in keeping with the finding of Davis, and contrasts with their frequency as reported by Latarjet and Bonnet. Of the 3 dissections in which these were seen, they occurred bilaterally in 2 instances and only on the left in 1 instance. All were short, fine fibers and ran almost transversely from sympathetic trunk to superior hypogastric plexus.

The fibers arising from the lumbar sympathetic ganglia proper emerge from the medial aspect of the ganglia as fine though extremely tough filaments which are usually single, though occasionally multiple. They course downward and medially posterior to the common iliac artery of that side and anterior to the vein. This relationship of artery, nerve, and vein is quite constant though in 5 dissections the nerve fibers passed posterior to both the artery and vein, and in 3 instances the fibers passed anterior to both structures. The nerves enter posteriorly at the superior aspect of the superior hypogastric plexus. In specimens in which a single "presacral nerve" occurs the fibers usually join the lateral borders of the nerve cord. In instances in which bilateral nerve cords occur, fibers join the lateral aspect of the ipsilateral nerve cord, while in the usual instance these nerves join the lateralmost portions of the plexus.

The sacral ganglia do not usually contribute fibers to the superior hypogastric plexus, though in some instances the first sacral ganglia may supply the plexus (6 per cent). Where this occurred the fibers arising from the first sacral ganglion coursed obliquely upward from the ganglion to join the plexus. In 2 instances short horizontal fibers from the first sacral ganglion joined the superior hypogastric plexus in addition to a full complement from the lumbar ganglion. The sacral ganglia usually intercommunicate via short, fine filaments which are immediately prevertebral and posterior to the fibroadipose lamina containing the fibers of the superior hypogastric plexus (41). The sacral nerves contribute many fibers to the lateral aspect of the Frankenhauser plexus.

The larger portion of the fibers of the plexus gradually diverge toward the lateral aspect of the interiliac trigone to terminate in the paired inferior hypogastric nerves. The chief innervation of the ureter is derived from these nerves. The inferior hypogastric nerves continue antero-inferiorly on the lateral pelvic wall and enter the uterosacral ligaments through which they course to the lateral aspect of the rectal ampulla, to terminate in the plexus of Frankenhauser. This rich sympathetic nerve fiber content of the uterosacral ligaments has not been sufficiently appreci-

Fig 1

ated and is of considerable clinical interest since one frequently observes edematous and especially tender uterosacral ligaments associated with various types of pelvic pathology.

There has been considerable discussion in the literature as to the existence of the Lee-Frankenhauser ganglion or plexus. Hovelacque referred to the anterior portion of the inferior hypogastric plexus as "the so called ganglion of Frankenhauser." Lee, Frankenhauser, Robinson, Hashimoto, Jung, and Kehr have all described the mass as a true sympathetic ganglion. It has been described as a grayish white plexus in the form of a quadrilateral mass whose limits and dimensions are not fixed, the medial surface of which is joined by the inferior hypogastric nerve. From the mesial aspect the pelvic visceral sympathetic innervation is derived, while the lateral aspect has an extensive anastomosis with the sacral nerves. Beautiful illustrations of dissections of the Frankenhauser plexus are given by Fontaine and Herrmann. The existence of this plexus, now well demonstrated anatomically, has been confirmed clinically by successful novocain and alcoholic block of the Frankenhauser plexus area which is an accepted surgical procedure.

Fig. 2.

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 7.

The superior hypogastric plexus also contributes filaments to the periarterial plexuses of the neighboring arteries: superior hemorrhoidal, the middle sacral, the external iliac and all the branches of the hypogastric.

The several fine filaments to the superior hemorrhoidal artery pass laterally from the superior portion of the left aspect of the superior hypogastric plexus and enter the sigmoid mesocolon. They are distributed to the sigmoid and may send fine branches to the plexus of Frankenhauser.

Infrequently fine filaments join the middle sacral periarterial plexus. This is occasionally true of fibers to the external iliac artery (demonstrable in only 7 instances). The rarity of this occurrence coincides with the report of Davis who takes issue with the report of Latarjet and Bonnet in which these fibers were discussed as though a common finding.

A diagrammatic schema of the connections of the superior hypogastric plexus is given in Figure

The sensory or afferent fibers course in a manner which probably is similar to that of the

Fig 8

Fig 9

Fig 10

motor, or efferents, except that they go via the posterior roots to reach the nerve cells of the posterior root ganglia. The afferent fibers of all the pelvic viscera transverse the superior hypogastric plexus with the exception of the ovarian and possibly some of the fibers of the fallopian tube which according to the physiological and anatomical researches of Labate and Reynolds "have no connection by way of the superior hypogastric plexus, nor do they traverse the inferior mesenteric ganglia or the lower aortic plexus" (38). This observation is of considerable clinical importance, and is borne out by the results of sympathetic nerve block. The wider recognition of this contribution will call a halt to the needless (and of course unsuccessful) attempts to relieve pain of ovarian origin by superior hypogastric sympathectomy. The afferent nerves from the ovary are contained in the periarterial ovarian plexus and reach the tenth thoracic level of the spinal cord (Kuntz). The ovarian plexus is found in the suspensory ligament of the ovary and is joined by an external tubular branch from the fallopian tube. Five or six efferents of the tubular branch course through the broad ligament and reach the lateral aspect of the periarterial uterine plexus.

The uterine afferent fibers traverse the Frankenhauser and then the superior hypogastric plexuses to reach the cord at the level of the first lumbar to tenth thoracic segment (Kuntz). A detailed and excellent résumé of our current knowledge of the innervation of the uterus is given by Reynolds while a clear exposition of the inner-

Fig 11

vation of the bladder may be found in McLellan's excellent monograph.

MORPHOLOGY OF THE PLEXUS

The superior hypogastric plexus is always found within the interiliac trigone, an area bounded by the bifurcation of the aorta above, the common iliac arteries laterally, and a line connecting these vessels at the promontory of the sacrum below. There is usually a plexus, uncommonly bilateral cords, and rarely a single "presacral" nerve. The plexus is triangular in shape with its apex up-

Fig. 2.

Fig. 3.

Fig. 4.

Fig. 5

Fig. 6.

Fig. 7

The superior hypogastric plexus also contributes filaments to the periaarterial plexuses of the neighboring arteries: superior hemorrhoidal, the middle sacral, the external iliac and all the branches of the hypogastric.

The several fine filaments to the superior hemorrhoidal artery pass laterally from the superior portion of the left aspect of the superior hypogastric plexus and enter the sigmoid mesocolon. They are distributed to the sigmoid and may send fine branches to the plexus of Frankenhauser.

Infrequently fine filaments join the middle sacral periaarterial plexus. This is occasionally true of fibers to the external iliac artery (demonstrable in only 7 instances). The rarity of this occurrence coincides with the report of Davis who takes issue with the report of Latarjet and Bonnet in which these fibers were discussed as though a common finding.

A diagrammatic schema of the connections of the superior hypogastric plexus is given in Figure 1.

The sensory or afferent fibers course in a manner which probably is similar to that of the

mately 0.3 cm) The width of the base of the trigone averages approximately 7 centimeters (5.8 to 7.5 cm) and tends to be wider in the female than in the male (by approximately 0.5 cm) This is in keeping with the normal divergence of the common iliac arteries from the bifurcation of the abdominal aorta, which occurs at an angle of 60 degrees in the male and 68 degrees in the female It is of interest to note that the dimensions of the trigone were exactly similar in the negro and white female, however, in males the trigone tends to be narrower and longer in the negro than in the white

The trigone normally contains the left common iliac vein, the middle sacral artery and veins, and the right ureter On the left border of the trigone the inferior mesenteric artery and its sigmoid branch enter the root of the pelvic mesocolon Finally, a fairly tough retroperitoneal connective tissue layer, into which the fibers of the superior hypogastric plexus are incorporated, lies within this area

The left common iliac vein runs parallel to the inferior (medial) margin of the left common iliac artery and courses upward and to the right, ascending posterior to the right common iliac artery to join the right common iliac vein in the formation of the vena cava The left common iliac vein thus occupies a considerable portion of the upper and left aspect of the trigone The vein is immediately subjacent to the overlying (anterior) layer of fibrous and fatty tissue in which the fibers of the superior hypogastric plexus are found and thus constitutes a surgical hazard of marked importance, especially when it is remembered that the wall of the vein is extremely thin Fortunately, the fibrocellular layer which is firmly adherent in the remainder of the trigone is very loosely adherent to the vein and may be easily separated from it. An appreciation of the surgical importance of this fact is heightened when it is recalled that in 9 per cent of this series the entire superior hypogastric plexus is shifted to the left and occupies an area solely in the left half of the trigone being markedly condensed anterior to the left common iliac vein In performing a superior hypogastric sympathectomy the surgeon working "over" (i.e., anterior to) the vein takes advantage of this loose connection of the nerves to the vein, in an effort to avoid injury to the vessel Injury to the vein has been reported (1)

The middle sacral artery and its accompanying veins descend from the bifurcation of the aorta to the tip of the coccyx The artery passes downward in the interiliac trigone which it tends to bisect, though occasionally it occupies a position

slightly in the left half of the trigone Within the trigone it lies successively upon the intervertebral disc between the fourth and fifth lumbar vertebrae, and the anterior aspect of the body of the fifth lumbar vertebra It is posterior to the connective tissue layer which contains the nerve fibers, and may be palpated through this layer The artery is not infrequently confused with a "single presacral nerve" type of superior hypogastric plexus and occasionally has been extirpated for the plexus It is interesting to note that the artery which is *not frequently visually obvious* can almost invariably be palpated, while the *nerve fibers* of the superior hypogastric plexus which *are frequently visually obvious* through a transparent peritoneum can not be identified by the palpating finger When this point is appreciated more fully, the incidence of extirpation of the middle sacral artery for the "presacral nerve" will markedly decrease An appreciation of the fact that the existence of a "presacral nerve" is in itself a rarity will also cause a cessation of the extirpation of a single cord area, and lead to the universal adoption of the policy of extirpating the entire interiliac fibrocellular tissue for removal of the superior hypogastric sympathetic plexus

The right ureter is exposed in the interiliac trigone, where it crosses the right common iliac artery just superior to its bifurcation into the external iliac and hypogastric arteries Fortunately, the right ureter is firmly adherent to the posterior surface of the peritoneum and is usually retracted with the peritoneum when it is reflected laterally, whereas the nerve fibers are incorporated into and firmly adherent to the subjacent fibrocellular layer of retroperitoneal connective tissue Thus the ureter can be identified and injury to it avoided In certain instances in which a type III mesocolon exists (*vide infra*) and it is necessary to retract the mesocolon sharply to the left, or when a type II pelvic mesocolon exists which must be retracted far to the left in order to remove it from the operative field, the ureter may be displaced mesially and be more liable to injury The left ureter is normally found entirely outside of the interiliac trigone and is rarely subject to injury in superior hypogastric sympathectomy

The inferior mesenteric artery runs downward from its origin about 3.5 centimeters superior to the bifurcation of the aorta, running obliquely and to the left, anterior to the lower portion of the abdominal aorta, and the left common iliac artery It descends into the pelvis between the layers of the sigmoid mesocolon to terminate on the rectum as the superior hemorrhoidal artery Its sigmoid branches run downward and to the left to enter

ward, representing the convergence of the intermesenteric nerves, and its base inferiorly where the main groups of nerve fibers diverge to terminate in the inferior hypogastric nerves. The position of the nerves whether as single cords or various plexus patterns is always prelumbal and never presacral.

When the intermesenteric nerves fuse at the apex of the interiliac trigone and continue without divergence until the very base of the trigone the resultant pattern is a single nerve cord, the so called presacral nerve. This is relatively uncommon—3 per cent in this series (Fig. 2). Even this single presacral nerve pattern may be classified as a plexus, if one considers the microscopic studies of Elaut, who was able to demonstrate clearly in transverse sections of the interiliac fibroadipose layer at least 4 or 5 separate islets of nerve tissue which are lost in the fat infiltrated subperitoneal membrane and have no reciprocal connections. In 2 per cent of our dissections the intermesenteric nerves enter the trigone, slightly separated and after continuing down for 1 to 1.5 centimeters join to form a single nerve which bifurcates at the base of the trigone (Fig. 3). The intermesenteric nerves may enter the interiliac trigone widely separated and continue downward in this relationship to the base of the trigone where they continue as the inferior hypogastric nerves, thus giving a bilateral (or double) cord pattern (Fig. 4). When this occurs, the cords have a number of very fine filamentous connections demonstrable throughout the length of the interiliac trigone (8 per cent).

Plexus patterns occur (4 per cent) wherein the lateral components are sharply marked but there are numerous heavy connecting fibers, and though the nerve fibers when inadequately dissected appear as a single flat band, careful dissection reveals a plexus (Figs. 5 and 6).

In many instances (39 per cent) the intermesenteric nerves upon entering the trigone fuse and almost immediately bifurcate to diverge at an acute angle. The diverging nerve cords are connected by many fibers and a narrow triangular pattern results (Fig. 7). In contrast to the more frequent (35 per cent) and similar though wider triangular pattern and the relatively rare (1 per cent) spider web pattern (Fig. 8) which is found when the divergence is marked and the connecting fibers are numerous and fine. In only 2 dissections (1 per cent) were arch shaped patterns encountered (Fig. 9).

The plexus may be shifted so as to occupy position solely to the left of the midline (Figs. 10 and 11). However the infrequency (8 per cent) of

the occurrence of this left-sided shift certainly makes unacceptable Reynolds' statement that "the nerves which comprise the so called hypogastric nerve pass caudally a little to the left of the midline. These left-sided plexuses were frequently found to be immediately adjacent to the left common iliac artery and the root of the sigmoid mesocolon. This is of considerable surgical interest since the extirpation of the retroperitoneal fibro-adipose tissue in the central portion of the interiliac trigone would fail to remove the nerve fibers constituting this type of plexus. An appreciation of the foregoing fact and that a single "presacral" nerve rarely exists—that the superior hypogastric plexus is always prelumbal and frequently occupies the entire interiliac trigone will cause fewer failures to be reported after superior hypogastric plexus sympathectomy. The incomplete extirpation of the plexus, the improper selection of cases and to a lesser extent the occurrence of neuromas in the remaining nerve stumps being the chief causes of poor results in surgery of the superior hypogastric plexus.

In 8 per cent of the subjects the intermesenteric nerves continued into the trigone as multiple parallel bands, frequently fusing just before reaching the promontory of the sacrum to form the inferior hypogastric nerves. These multiple parallel cords or bands were connected by many fibers.

After consideration of the large variety of patterns and the variations within each pattern group one can well endorse the statement: "It is difficult to find two plexuses with the same anatomical architecture" (Labate).

SURGICAL ANATOMY

A consideration of the surgical anatomy of the superior hypogastric plexus necessitates an appreciation of (1) the interiliac trigone in which the fibers of the plexus are always found (2) the normal contents of the trigone (3) abnormal contents of the trigone and finally (4) the variations in the pelvic mesocolon.

The interiliac trigone has for its apex the bifurcation of the abdominal aorta, its lateral boundaries the common iliac arteries, and its base corresponds to a line joining the two common iliac arteries at the level of the promontory of the sacrum. The trigone therefore embraces an area comprising the lower half or third of the fourth lumbar vertebra, the intervening intervertebral cartilaginous disc and the fifth lumbar vertebra. Its length varies with the level of bifurcation of the abdominal aorta and averages approximately 6 centimeters (4.9 cm. to 6.4 cm.). It tends to be slightly more elongated in the male (by approxi-

mately 0.3 cm) The width of the base of the trigone averages approximately 7 centimeters (5.8 to 7.5 cm) and tends to be wider in the female than in the male (by approximately 0.5 cm) This is in keeping with the normal divergence of the common iliac arteries from the bifurcation of the abdominal aorta, which occurs at an angle of 60 degrees in the male and 68 degrees in the female It is of interest to note that the dimensions of the trigone were exactly similar in the negro and white female, however, in males the trigone tends to be narrower and longer in the negro than in the white

The trigone normally contains the left common iliac vein, the middle sacral artery and veins, and the right ureter On the left border of the trigone the inferior mesenteric artery and its sigmoid branch enter the root of the pelvic mesocolon Finally a fairly tough retroperitoneal connective tissue layer, into which the fibers of the superior hypogastric plexus are incorporated, lies within this area

The left common iliac vein runs parallel to the inferior (medial) margin of the left common iliac artery and courses upward and to the right, ascending posterior to the right common iliac artery to join the right common iliac vein in the formation of the vena cava The left common iliac vein thus occupies a considerable portion of the upper and left aspect of the trigone The vein is immediately subjacent to the overlying (anterior) layer of fibrous and fatty tissue in which the fibers of the superior hypogastric plexus are found and thus constitutes a surgical hazard of marked importance, especially when it is remembered that the wall of the vein is extremely thin Fortunately, the fibrocellular layer which is firmly adherent in the remainder of the trigone is very loosely adherent to the vein and may be easily separated from it. An appreciation of the surgical importance of this fact is heightened when it is recalled that in 9 per cent of this series the entire superior hypogastric plexus is shifted to the left and occupies an area solely in the left half of the trigone being markedly condensed anterior to the left common iliac vein In performing a superior hypogastric sympathectomy the surgeon working "over" (i.e., anterior to) the vein takes advantage of this loose connection of the nerves to the vein, in an effort to avoid injury to the vessel Injury to the vein has been reported (1)

The middle sacral artery and its accompanying veins descend from the bifurcation of the aorta to the tip of the coccyx The artery passes downward in the interiliac trigone which it tends to bisect, though occasionally it occupies a position

slightly in the left half of the trigone Within the trigone it lies successively upon the intervertebral disc between the fourth and fifth lumbar vertebrae, and the anterior aspect of the body of the fifth lumbar vertebra It is posterior to the connective tissue layer which contains the nerve fibers, and may be palpated through this layer The artery is not infrequently confused with a "single presacral nerve" type of superior hypogastric plexus and occasionally has been extirpated for the plexus It is interesting to note that the artery which is *not frequently visually obvious* can almost invariably be palpated, while the *nerve fibers* of the superior hypogastric plexus which *are frequently visually obvious* through a transparent peritoneum can not be identified by the palpating finger When this point is appreciated more fully, the incidence of extirpation of the middle sacral artery for the "presacral nerve" will markedly decrease An appreciation of the fact that the existence of a "presacral nerve" is in itself a rarity will also cause a cessation of the extirpation of a single cord area, and lead to the universal adoption of the policy of extirpating the entire interiliac fibrocellular tissue for removal of the superior hypogastric sympathetic plexus

The right ureter is exposed in the interiliac trigone, where it crosses the right common iliac artery just superior to its bifurcation into the external iliac and hypogastric arteries Fortunately, the right ureter is firmly adherent to the posterior surface of the peritoneum and is usually retracted with the peritoneum when it is reflected laterally, whereas the nerve fibers are incorporated into and firmly adherent to the subjacent fibrocellular layer of retroperitoneal connective tissue Thus the ureter can be identified and injury to it avoided In certain instances in which a type III mesocolon exists (*vide infra*) and it is necessary to retract the mesocolon sharply to the left, or when a type II pelvic mesocolon exists which must be retracted far to the left in order to remove it from the operative field, the ureter may be displaced mesially and be more liable to injury The left ureter is normally found entirely outside of the interiliac trigone and is rarely subject to injury in superior hypogastric sympathectomy

The inferior mesenteric artery runs downward from its origin about 3.5 centimeters superior to the bifurcation of the aorta, running obliquely and to the left, anterior to the lower portion of the abdominal aorta, and the left common iliac artery It descends into the pelvis between the layers of the sigmoid mesocolon to terminate on the rectum as the superior hemorrhoidal artery Its sigmoid branches run downward and to the left to enter

Fig. 2.

Fig. 3.

the sigmoid mesocolon and are distributed to the sigmoid. As they enter the root of the pelvic mesocolon they lie on the left border of the interiliac trigone and in instances in which a type III mesocolon exists they assume importance in superior hypogastric sympathectomy since it is necessary to dissect between the layers of the mesocolon to expose the interiliac trigone, and in such a dissection these vessels may be injured.

The interiliac trigone is entirely retroperitoneal. Its peritoneal covering on the right is reflected to the lateral walls of the pelvis and spreads downward to the anterior surface of the sacrum. On the left the peritoneum descends from the abdomen to the rim of the pelvis where it is reflected over the sigmoid colon and the upper portion of the rectum whence it is again reflected to the inner aspect of the anterior abdominal wall. The peritoneal layers which have thus ensheathed the pelvic colon approach each other superomedially and fuse to form a true mesentery of the pelvic mesocolon. Between the two layers of the pelvic mesocolon run the vascular and nervous supply of that section of the bowel.

There is considerable variation in the length and the position of the line of attachment of the pelvic mesocolon. In general three main types may be described.

Type I. A short mesocolon easily retracted to the left and allowing adequate exposure of the interiliac trigone (Fig. 13).

Type II. A long mesocolon which may readily be shifted or retracted to expose the interiliac trigone (Fig. 14).

Type III. A long mesocolon, the leaves of which embrace the interiliac trigone, its attachment being along the midline. This type of mesocolon makes difficult the exposure of the interiliac trigone, particularly when dissection between the leaves of the mesocolon is resorted to in order to expose the superior hypogastric plexus (Fig. 15). This type of dissection endangers the vascular and nervous supply which is transmitted through the mesocolon to the bowel it ensheathes. Dissection between the layers of the mesocolon should be avoided and the superior hypogastric plexus exposed by incision parallel to the root of the mesocolon and through both of its layers (Eliant). In a series of 50 dissections Eliant reported the occurrence of 78 per cent of the first type of mesocolon, 24 per cent of the second, and 8 per cent of the third. Roussel reported type III mesocolon in 15 per cent of his cases, while Cotte found it in only 1 per cent. Bernard and Theodoresco and Labate have each reported its occurrence in 1 case.

In this series in females type I occurred in 75 per cent, type II in 25 per cent. Type III did not occur. The incidence was similar in the negro and the white. However in males there was a greater occurrence of the type III mesocolon in the negro, the percentages being 8 of type I, 14 type II, and

Fig 14

Fig 15

5 type III in the white, while they were 70 type I, 16 type II, and 14 type III in the negro. As previously noted this was the only significant racial difference encountered.

In addition to these normal relations of the interiliac trigone, various anomalies have been encountered. In 4 dissections accessory ureters were found which traversed the trigone. Davis similarly reported occurrences of accessory ureters in 3 of the 12 operative cases he studied. In several of our dissections in the infant, the right ureter bent rather sharply toward the midline and so was included in the trigone and subject to injury. This finding is confirmed by Labate, who included 52 infants in his report of 75 dissections.

In 3 of our dissections the transverse duodenum was found anterior to the interiliac trigone. In 1 of these cases the other abdominal viscera were also ptosed. In the 2 others the abdominal viscera were normally located with the exception of the duodenum. The left common iliac vein in 14 per cent of our dissections had sharp S-like deviations toward the midline, and projected into the interiliac trigone to well beyond the midline occupying the entire upper and left half of the trigone. In 2 per cent of this series the left common iliac artery had a similar deviation, and occupied a position which would normally be well within the interiliac area. In these 2 instances the artery was partially covered anteriorly with the hypogastric plexus which in each of these instances was of the spider-web pattern, and occupied an area comparable to the normal trigonal area. In

1 subject the right and left common iliac veins joined to form the inferior vena cava anterior to the bifurcation of the abdominal aorta. The interiliac trigone in this instance was bounded by the vena cava superiorly and the common iliac veins laterally, the aorta and common iliac arteries being posterior to these structures. The superior hypogastric plexus in this instance was of the multiple cord pattern and within the venous triangle.

The discussion of a very important vascular anomaly which occurs with surprising frequency and which has gained little attention in the literature has been left for last. The majority of investigators are silent on the subject. Elaut states "One must bear in mind a certain anomaly of the blood vessels occurring not infrequently within the interiliac trigone. In our rather small series of cases we met this condition twice, namely a large, pencil-sized vein arose from the left common iliac vein, proceeded directly across the trigone and joined the opposite wall of the pelvis at a spot close to the bifurcation of the common artery. The veins lay on the periosteum, the nerves cross it obliquely, being adherent in a few places." In the series of dissections herein reported anomalous veins of this type were found 26 times! Seventeen occurred in the male, and 9 in the female, with the distribution even between the negro and white. In several instances the vein was half as large as the common iliac vein, while in the greater number of cases the vein was of much smaller size. In 3 instances these large veins arose within the substance of the psoas

Fig. 6.

Fig. 7.

muscle on the opposite side of the pelvis and crossed the interiliac trigone to empty into the left common iliac vein. Many of the smaller veins could be traced directly from the peritoneum traversing the interiliac trigone and emptying into the common iliac vein. Several of the veins were in the nature of accessory hemorrhoidal veins which ran retroperitoneally to the left of the midline in the interiliac trigone to empty into the left common iliac vein. These veins are a distinct surgical hazard, and should be given much greater emphasis. Further investigations of their exact origins are in progress (Figs. 16-17).

RESULTS OF EXTIRPATION OF THE SUPERIOR HYPOGASTRIC PLEXUS

A detailed account of the physiology of the superior hypogastric plexus does not come within the province of this paper. However one hesitates to omit some comments on the results of extirpation of the superior hypogastric plexus on menstruation and on parturition which are currently not widely appreciated. Despite many expressed fears to the contrary Pearce has recently adequately stressed the lack of harm of this procedure in reference to childbirth and concluded, "Presacral neurectomy has no influence on any part of the process of pregnancy. In some patients, probably only a small proportion, the first stage of labor is painless and rapid or else unobserved. These conclusions are substantiated by the observations of many others (Collins, Cotte, Davis, Donaldson, Keene, Learmonth, Fontaine and Hermann, and Wetherell)."

The menstrual cycle is unaffected by superior hypogastric plexus sympathectomy though the period immediately following the operation may be prolonged (Fontaine and Hermann).

The physiology of the superior hypogastric plexus in relation to the urinary system has been adequately stressed by McLellan and Learmonth.

SUMMARY

A report is given of 50 personal dissections of the superior hypogastric plexus in 30 females, 14 negro and 6 white and 30 males, 16 negro and 14 white. The surgical anatomy of the interiliac trigone, an area bounded by the bifurcation of the abdominal aorta, the common iliac arteries, and the promontory of the sacrum, which contains the superior hypogastric plexus, is described. Stress is laid upon:

1. The wide variation in the configuration of the superior hypogastric plexus and the predominance of plexus patterns, 88 per cent the uncommon finding of bilateral nerve cords, 8 per cent and the relative rarity of the single "pre-sacral nerve," 4 per cent.

2. The disposition of the normal contents of the interiliac trigone: (a) the left common iliac vein (b) the middle sacral vessels (c) the right ureter and (d) the fibrocellular connective tissue lamina which contains the superior hypogastric plexus (Fig. 2).

3. The anomalies of the interiliac region: (a) accessory ureters (b) low lying transverse duodenum covering the anterior surface of the trigone; and (c) an anomalous vein which occurred in 16

dissections to which special emphasis is given (Figs 16 and 17)
 4 The variations in length and implantation of the sigmoid mesocolon with a description of the three types encountered (Figs 13, 14, and 15)

muscle on the opposite side of the pelvis and crossed the interiliac trigone to empty into the left common iliac vein. Many of the smaller veins could be traced directly from the peritoneum traversing the interiliac trigone and emptying into the common iliac vein. Several of the veins were in the nature of accessory hemorrhoidal veins which ran retroperitoneally to the left of the midline in the interiliac trigone to empty into the left common iliac vein. These veins are a distinct surgical hazard, and should be given much greater emphasis. Further investigations of their exact origins are in progress (Figs. 6-17).

RESULTS OF EXTIRPATION OF THE SUPERIOR HYPOGASTRIC PLEXUS

A detailed account of the physiology of the superior hypogastric plexus does not come within the province of this paper. However, one hesitates to omit some comments on the results of extirpation of the superior hypogastric plexus on menstruation and on parturition which are currently not widely appreciated. Despite many expressed fears to the contrary Pearce has recently adequately stressed the lack of harm of this procedure in reference to childbirth and concluded, "Presacral neurectomy has no influence on any part of the process of pregnancy. In some patients, probably only a small proportion the first stage of labor is painless and rapid or else unobserved. These conclusions are substantiated by the observations of many others (Collins, Cotte Davis, Donaldson, Keene, Learmonth, Fontaine and Herrmann, and Wetherell).

The menstrual cycle is unaffected by superior hypogastric plexus sympathectomy though the period immediately following the operation may be prolonged (Fontaine and Herrmann).

The physiology of the superior hypogastric plexus in relation to the urinary system has been adequately stressed by McClellan and Learmonth.

SUMMARY

A report is given of 150 personal dissections of the superior hypogastric plexus 30 females, 14 negro and 6 white, and 30 males, 96 negro and 34 white. The surgical anatomy of the interiliac trigone, an area bounded by the bifurcation of the abdominal aorta, the common iliac arteries, and the promontory of the sacrum, which contains the superior hypogastric plexus, is described. Stress is laid upon

1. The wide variation in the configuration of the superior hypogastric plexus and the pre-dominance of plexus patterns, 88 per cent, the uncommon finding of bilateral nerve cords, 8 per cent, and the relative rarity of the single "presacral nerve," 4 per cent.

2. The disposition of the normal contents of the interiliac trigone: (a) the left common iliac vein (b) the middle sacral vessels, (c) the right ureter and (d) the fibrocellular connective tissue lamina which contains the superior hypogastric plexus (Fig. 15).

3. The anomalies of the interiliac region: (a) accessory ureters, (b) low lying transverse duodenum covering the anterior surface of the trigone and (c) an anomalous vein which occurred in 20

dissections to which special emphasis is given (Figs 16 and 17)

4 The variations in length and implantation of the sigmoid mesocolon with a description of the three types encountered (Figs 13, 14, and 15)

RESULTS OF EXTERPATION OF THE SUPERIOR HYOAGASTRIC PLEXUS

A detailed account of the physiology of the superior hypogastric plexus does not come within the province of this paper. However, one hesitates to omit some comments on the results of extirpation of the superior hypogastric plexus on menstruation and on parturition which are currently not widely appreciated. Despite many expressed fears to the contrary Pearce has recently adequately stressed the lack of harm of this procedure in reference to childbirth and concluded, "Pre-sacral neurectomy has no influence on any part of the process of pregnancy. In some patients, probably only a small proportion, the first stage of labor is painless and rapid or else unobserved. These conclusions are substantiated by the observations of many others (Collins, Cotte, Davis, Donaldson, Keene, Learmonth, Fontaine and Herrmann, and Wetherell).

The menstrual cycle is unaffected by superior hypogastric plexus sympathectomy though the period immediately following the operation may be prolonged (Fontaine and Herrmann).

The physiology of the superior hypogastric plexus in relation to the urinary system has been adequately stressed by McClellan and Learmonth.

SUMMARY

A report is given of 50 personal dissections of the superior hypogastric plexus: 20 females, 14 negro and 6 white and 30 males, 96 negro and 34 white. The surgical anatomy of the interiliac trigone, an area bounded by the bifurcation of the abdominal aorta, the common iliac arteries, and the promontory of the sacrum, which contains the superior hypogastric plexus, is described. Stress is laid upon:

1. The wide variation in the configuration of the superior hypogastric plexus and the pre-dominance of plexus patterns, 83 per cent. the uncommon finding of bilateral nerve cords, 8 per cent. and the relative rarity of the single "pre-sacral nerve", 4 per cent.
2. The disposition of the normal contents of the interiliac trigone: (a) the left common iliac vein (b) the middle sacral vessels (c) the right ureter and (d) the fibrocellular connective tissue lamina which contains the superior hypogastric plexus (Fig. 2).
3. The anomalies of the interiliac region: (a) accessory ureters (b) low lying transverse duodenum covering the anterior surface of the trigone and (c) an anomalous vein which occurred in 26

Fig 2 Case 2

ically," the only *safe* way to treat that patient further is to take him off iodine *gradually*. Then after a period of time, say 2 to 4 months, when the thyroid will again respond the patient can be operated upon safely under its influence.

With this in mind, we suggest the following regimen to be used in such cases. When it is obvious that a patient will not have an "iodine remission" he is weaned from it, so to speak, that is, the iodine is stopped gradually so that a crisis will not occur. The weaning process may take a few days or it may take weeks. The symptoms may become slightly aggravated but

bed rest and sedation have been found ample to control them. The x-ray may also be helpful. Second, the patient is placed on an iodine-free, or low in iodine, diet but high in proteins, vitamins, and carbohydrates. It must be emphasized again and again to the patient not to take iodine or any foods containing it and to take no medicine other than that prescribed. The patient may be seen at weekly intervals for the first month or so and then every month until sufficient time has passed, 2 to 4 months. At the end of this time he is again hospitalized and prepared in the usual manner for operation.

Fig 3 Case 3

SO CALLED IODINE RESISTANT* HYPERTHYROIDISM

J. E. KEARNS, J. M.D. F.A.C.S., and PAUL STARR, M.D. Chicago, Illinois

THE operative mortality rate in well controlled cases of hyperthyroidism is still between 1 and 5 per cent depending upon the co-ordination between the medical and surgical divisions and the number of severely ill patients included in the series studied. We do not consider the patient with Graves disease an emergency until he has been started on iodine even the acutely ill patient can be controlled for a period of time with diligent medical and roentgen therapy. A few cases of toxic goiter between 5 and 10 per cent, will not respond to the usual preoperative iodine therapy and some appear to become definitely worse with its use. These patients are usually in the older age group and it is our opinion as well as that of others, that the mortality and morbidity following operation in these cases are higher.

We wish to show that these so called 'iodine resistant' or 'iodine fast' cases will respond to a specific regimen of therapy that they are not emergency cases, but that with time they can be operated upon under the influence of iodine. Blank, Means, and others have definitely found, both by clinical and pathological studies, that

some of these patients are in reality being controlled by iodine. There is no clinical evidence of this fact, however, because the use of the iodine is preventing a crisis. Crisis, in itself, would suggest that great caution should be exercised in anticipating operation at this time.

A search of the literature reveals that this condition was not described until after Marine and Kimball in 1917 advocated the use of iodine and iodized salt in the prevention of "endemic goiter" and when Plummer and his associates recommended in 1923 the use of Lugol's solution in the preoperative and postoperative care of toxic patients. It is obvious to us that some of these patients have been taking sufficient iodine so long that the thyroid is no longer able to respond to its use. The source of the iodine may be salt, food, old family remedies, or patent medicine. W. O. Thompson et al. have shown that the minimal effective dose of compound solution of iodine varies between 6 and 10 milligrams a day. The average person consumes about 1.5 milligrams of iodine a day in table salt alone without considering other food sources. It is a well known fact that if a patient has been receiving Lugol's solution or some other iodine substance for a long time in an attempt to manage his condition "med-

HAZARDS OF FIRE AND EXPLOSION OF ANESTHETIC AGENTS

II In the Presence of the Cautery

BARNETT A. GREENE, M.D., Brooklyn, New York

WE have described, in a preceding report,¹ the hazard of anesthetic combustion during the use of x-ray apparatus. Like x-ray equipment, the cautery is a common source of danger that is always condemned by writers on anesthetic explosions but without sufficient explanatory detail to force every anesthetist and surgeon to realize how serious is the danger and how great is the need for accurate and minute knowledge of the facts of anesthetic combustions. In this paper we deal at length with the information required of the anesthetist and the surgeon which will enable them to use the actual cautery safely and yet without unnecessary restrictions.

We also discuss here, because it is most fitting, ignition by such obviously hot objects as the cautery, gas flame, match light, or cigarette, also mentioned are the small group of fires caused by the application of the cautery to surgical fields prepared with ethyl chloride spray anesthesia, or with inflammable skin cleansers like ether or alcohol, or with inflammable skin antiseptics like the various tinctures.

The actual cautery is an important surgical instrument employed in almost every operating room at least several times a week. Familiarity with the cautery has bred contempt for this hazard. On the other hand, unreasonable restrictions against the use of the cautery should not be placed in the way of the surgeon desiring to employ it.

Why have there been at least 55 known and wholly preventable anesthetic fires and explosions ignited by such an obvious hazard as a cautery, flame, or other hot object? We think the explanation is to be sought in the following reasons:

1 Ignorance of an elementary knowledge of anesthetic combustion. Our personal survey has

Dr. Greene is director of anesthesia, Prospect Heights Hospital, Brooklyn, N. Y.; anesthetist, Brooklyn Cancer Institute, Kings County Hospital; chairman, Subcommittee on Anesthetic Hazards, American Society of Anesthetists; Diplomate, American Board of Anesthesiology.

¹This is the second of a series of papers on the explosion and fire hazard of anesthesia based on a study of the literature and of the case reports secured by the Committee on Anesthetic Hazards. Dr. Barnett A. Greene, chairman, this group acting as a subcommittee of the Research Committee of The American Society of Anesthetists, Inc.

found an astonishingly large number of surgeons and anesthetists who lack basic and even rudimentary information on this subject.

2 Indifference toward the hazard because of past good fortune while using set-ups in the operating room which we consider dangerous.

3 A paucity and inflexibility of anesthetic methods available to many surgeons who must use the cautery. (*This is the usual reason for the use of hazardous techniques*.)

In short, the cause is almost always ignorance. The cure must be education and elevation of the standards of anesthetic training and practice.

PHYSICAL AND CHEMICAL DATA

The fundamental physical and chemical data included in the first report (22) will not be repeated, although they should be familiar to all who read this and subsequent reports. We shall, however, present such supplementary facts as have a special bearing on the particular type of hazard under discussion.

The following information, added to the basic scientific facts presented in our first paper, should be required knowledge of every anesthetist, and also of every surgeon who desires or is obliged to dictate the choice of anesthetic procedures.

1 The minimum ignition temperatures at 0 degrees C. are shown in Table I.

TABLE I—MINIMUM IGNITION TEMPERATURES

	In air	In oxygen
Diethyl ether	304	182
Dimethyl ether	399	327
Ethylene	490	485
Cyclopropane	498	
Ethyl chloride	517	468

It is apparent that the presence of a high concentration of oxygen instead of air (21 per cent oxygen and 79 per cent nitrogen) lowers the minimum ignition temperature of a combustible agent, nitrous oxide lowers it even more than does oxygen (8).

As shown in Table I ether-oxygen and ether-air mixtures are more easily ignited than similar mixtures of ethylene or cyclopropane.

Brief reviews of 3 cases with their clinical records are presented to show the efficacy of this method. A third case is presented to demonstrate the value of the method in a patient who developed a preoperative complication that made postponement of surgery to a more opportune time necessary.

CASE. Mrs. H. H., 50 years of age, sought relief for palpitation, loss of weight, nervousness (hysteria at times), heat intolerance, and eye trouble. There was no history of iodine medication for years. Physical examination showed nervous, acutely ill female; pulse, 90; blood pressure, 80/80. The skin was hot and moist. No definite pigmentation over the tarsus. She presented moderate exophthalmos and had numerous eye signs. A firm thyroid was palpable, but there was no bruit. Laboratory reports were essentially normal except for metabolic rate of plus 54 per cent. From study of the chart (Fig. 1) it can be seen that on Mrs. H.'s first admission to the hospital there was little, if any, response to 28 days of iodine therapy so this was stopped gradually and the patient was discharged from the hospital. Four months later she was readmitted to the hospital and was operated upon successfully following an iodine remission. It is interesting to note the postoperative reaction following the abrupt withdrawal of iodine and its subsidence when iodine was started again.

CASE 2. Mrs. A. G., 46 years of age, also had rather typical history and findings of toxic goiter. With no previous story of iodine medication. The physical findings showed nervous, well developed, white female; pulse, 95; blood pressure, 58/70. The thyroid was enlarged, with slight bruit, firm, and nodular. In this patient's clinical course (Fig. 2) she was one of the few that have seen who developed more severe toxic symptoms while on iodine,

but after period of 3 1/2 months (about 12 weeks) were able to secure remission and she was safely operated upon.

CASE 3. Mrs. J. F., aged 50 years (Fig. 3) presented clinical symptoms and findings of Graves' disease. She developed an acute upper respiratory infection on the 11th day of preoperative preparation, and had escaped from the iodine effect by the time this was controlled. The patient was sent home on an iodine free diet, etc. for 3 months and has since been readmitted to the hospital and successfully operated upon.

CONCLUSION

The 3 cases presented show the benefit of the conservative handling of so called iodine resistant cases as well as in one in which postponement of operation was necessary.

We realize the difficulty of managing these patients unless they can be kept under constant observation but do believe that in cases not emergencies, the type of care described will result in a further reduction in mortality and morbidity.

may safely apply the cautery in the region of the head after an inflammable anesthetic mixture has been administered. This situation, expected or unexpected, is frequently encountered. Many case reports testify to the incorrect answer to the question and record the consequent death of the patient.

The duration of the period in which an etherized patient exhales an inflammable concentration after the administration of ether has ceased depends on the minute-volume of respirations and the degree of saturation of the patient with ether. The expired breath of a patient in third stage anesthesia immediately after the end of administration of ether-air, ether-oxygen or ether-nitrous oxide-oxygen is probably combustible. This may be inferred from the data of anesthetic concentrations compared with the figures for explosive concentrations, for the concentration of ether for the induction and maintenance of anesthesia is at least 2.5 per cent, more often 3.5-4.5 per cent (1), and the lower limit of inflammability of ether in air is 1.85 and of ether in oxygen is 2.10 (21). Furthermore, as long as the patient remains in full surgical anesthesia we might expect to find an inflammable percentage of ether in the breath. This deduction is based on the data quoted by Beecher from the research work on dogs by Haggard and Robbins (1). They have shown that surgical ether anesthesia is induced and maintained with 3.7-4.5 per cent ether in the respired air, that this produces a blood ether concentration of 100-120 milligrams per 100 cubic centimeters of blood, and that light (first plane) surgical anesthesia corresponds with an arterial blood ether content of 115 milligrams per 100 cubic centimeters (1).

These inferences are contradicted (a) by the statement of Hewer that "the exhalations of an etherized patient are probably never inflammable or explosive" (10), and by (b) the report of Hasler (17) that samples of air taken at a distance of 2 inches from an open mask, after an operation had been in progress for an hour and 10 ounces of ether had been used, were noncombustible, and (c) by the work of Featherstone and Morgan (6, 27) who were unable to ignite, by spark or flame (1) specimens of expired air and ether collected immediately after the withdrawal of a heavily impregnated ether mask, (2) collected expirations during deep ether anesthesia, or (3) a mixture exhaled immediately after a deep inspiration of a strong ether air mixture.

Despite these negative and reassuring reports we must take a skeptical attitude because in addition to the danger theoretically inferred from explosive and anesthetic concentrations, we possess

case reports which testify to the reality of the danger. Even Featherstone is not sure of the safety of his findings as indicated by his advice that the patient under ether should be allowed to take a dozen breaths of fresh air after the administration of ether has ceased (9). We feel, however, that such a practice is too unreliable (because the rate of exhalation of ether may be very variable) on which to depend for an act so hazardous as applying a cautery in or near the head of a patient who has had ether.

To resolve the inevitable doubt at a time when it is urgent and important to know positively whether or not the expirations of a patient are inflammable, we recommend the simple method suggested by Flagg (10). He has advised the withdrawal of a sample of the expired pharyngeal air by means of a bulb syringe and the testing of the inflammability of its contents in an adjoining room by emptying the syringe across an alcohol lamp flame. An inflammable mixture changes the color of the flame by taking fire, an explosive mixture harmlessly "pops." In place of the 2 inch rubber bulb fitted with the glass top of an eye dropper which Flagg has used, we prefer, as safer and simpler, an all-rubber ear syringe of the same size. There is no possibility then of shattering glass or of the glass tip slipping out of the bulb handle. This test is simple, safe, and positive in its results. If the test, which we shall hereafter refer to as the Flagg test, is negative then "the field is absolutely safe for cauterization at that time" (10).

An important fact, related to the safety of using a cautery near the head of an etherized patient, is that the stomach may contain an inflammable concentration of the anesthetic swallowed during induction. This is much more likely with ethylene and cyclopropane than with ether (which is administered in concentrations not much above the minimal limit). The stomach bubble of combustible gases may be regurgitated during the period when the patient is breathing fresh air and is ascending from surgical anesthesia. At this critical moment the cautery might be applied in or near the head of the patient. Thus there might occur an explosion under conditions considered safe because the patient had been allowed to take a dozen breaths of fresh air and the Flagg test had been found negative only a few seconds or a minute before. Therefore if an igniting agent such as a cautery or hot metal dental syringe must be used in the upper respiratory tract after the patient has received a combustible anesthetic it is necessary to deflate the stomach by intubation before securing a negative Flagg test.

The minimum ignition temperatures of liquid ether and mixtures of ether with air, oxygen or nitrous oxide are well below visible spark temperatures (3, 4, 13). Kirby Thomas has found that certain mixtures of ether-air or ether-oxygen can be exploded at temperatures below 100 degrees C. (13).

The hot element of all cauteries can ignite any combustible anesthetic mixture. Many case reports have demonstrated this fact beyond doubt.

2. Electric cauteries present four points at which igniting temperatures may be produced: (a) the heated element, (b) the foot pedal switch, (c) the rheostat, and (d) the cord or terminals which may break because of frequent usage or become detached because of inadvertent pulling (19) thus producing sparking.

3. A knowledge of the densities of anesthetic gases and vapors is important in understanding the cautery hazard. As compared with air having a density of 1, ethylene has a density of 0.97, cyclopropane .45, ethyl chloride, 2.23, divinyl ether, 2.43, and diethyl ether 2.56 (2).

The rate at which a gas or vapor will diffuse or mix with air is inversely proportional to the square

root of its density (rate of diffusion $\propto \frac{1}{\sqrt{\text{Density}}}$)

for this reason anesthetics having low density such as ethylene will diffuse more rapidly into air than will ether vapor. This means that rich mixtures of ethylene on being discharged into an operating room will pass through the explosion range and become nonexplosive, other conditions being constant, sooner than a heavy vapor. A heavy vapor such as ether has a tendency to remain longer in its highly concentrated condition and on account of its greater density will tend to descend and accumulate at the floor level and under favorable circumstances may flow a considerable distance from the source of discharge. On account of these characteristics, the fire hazards are greater for vapors of this type. (21) Ether has been known to take fire at a measured distance of 5 feet from the source of escaping vapor (34).

It is because of its heavy density as well as its frequent administration in open techniques that we find ether to be the most often ignited anesthetic when the igniting agent is external to the anesthetic circuit, e.g. cautery faulty electrical apparatus, and flames.

The actual concentrations of ethylene in the atmosphere of operating rooms has been well studied by Cheney and Folkman. Based on several thousand readings made in 4 hospitals of modern construction but without unusual ventilating sys-

tems, the conclusions of their report are worth repeating here (4).

"a. At distances of 10 feet or more from the patient's head the concentrations were so small as to be indeterminable.

"b. No evidence of accumulation of ethylene percentages in any part of the operating room was found after the longest period of continuous anesthesia (with the partial rebreathing method of administration).

"c. Electric switches on the walls of the operating room were shown to be entirely harmless inasmuch as the maximum ethylene concentration at these points was less than 0.1 per cent.

"d. The only points where explosive concentrations of ethylene occurred were in the immediate vicinity of the face mask. The dangerous area extended to 1 foot above the face mask and 2 feet to the particular side of the mask toward which the expiratory vent pointed. Immediately to the side of the mask but on the side opposite that toward which the vent was directed the ethylene concentration was less than 1 per cent.

"e. With the vent of the exhalation valve pointed to the side, no concentration above the chest of the patient was found higher than 0.2 per cent in those cases in which the anesthetist used a cloth shield between the field of operation and the patient's head. These percentages were also reduced when the anesthetist used rebreathing.

"f. With the use of a cloth shield, proper adjustment of the exhaling vent and the technique employed by the anesthetist during these tests, it would appear that the cautery could be used in the abdomen with entire safety. (The technique used in these tests included a tightly fitting mask, exhalation vent directed to the side and not straight up and, most important, a large percent age of rebreathing.)

Since the time of these studies (1930) the method of complete rebreathing has become standard practice. With this method the atmosphere of the operating room is more likely to be free of an explosive concentration of ethylene or any other anesthetic, even in the region close to the mask. But sudden, unexpected breaks in the closed circuit because of vomiting, the need to use suction or to insert an airway preclude the possible use of the cautery or a flame near the head, neck, shoulders and chest, even with a perfectly closed circuit (a theoretical assumption that is frequently not attained in clinical practice).

4. Exact information on the combustibility of the expirations of a patient under anesthesia and the duration of its inflammable status is needed to enable the anesthetist to know when the surgeon

the patient, the type of surgery, or the limited experience and ability of the available anesthetist), then the following conditions should exist before the cautery is switched on

a A meticulously closed circuit method of administration should have been in use during the prior 10 minutes, an arbitrary but clinically determined safe period (13)

b The combustible anesthetic of choice, if combustible it must be, is ether-air by closed circuit administration because of its smaller tendency toward propagation and smaller range of explosibility as compared with ether, ethylene, or cyclopropane mixtures with high concentrations of oxygen or nitrous oxide Cyclopropane, ethylene and ether with oxygen are permissible, however

c The ventilation should have been arranged to increase the dispersion of anesthetic gases and vapors previously allowed into the atmosphere

The direction of ventilation should be away from the cautery and toward the patient's head

d The patient should be securely set in third stage anesthesia (deep first plane or deeper) to be certain that no vomiting occurs to break the closed circuit during the period of cauterization

e No part of the cautery, its wires, switch, or rheostat should be near the anesthetic apparatus

f A draped screen should be placed so that it will intervene between the head of the patient and the field of operation

g If doubt exists as to the freedom of the room from inflammable concentrations of anesthetics released into the air before the circuit of anesthetic administration is closed, then a "Flagg test" should be applied to the possible points of contact of the cautery apparatus with atmosphere

5 If the cautery is to be used on or in a hollow viscus in the abdomen, such as the bladder or stomach in addition to the precautions listed in paragraph 4, we advise, when ethylene, cyclopropane or acetylene is used, that one take pains to empty the viscus of its gaseous content just before the cautery is applied (13)

6 If the cautery is unexpectedly required in a case which has been inhaling a combustible anesthetic, the necessary precautions before the cautery is permitted are

7 If the field of operation is on or in the head, neck, chest or respiratory tract, the anesthetic should be changed to another but noncombustible type while the respiratory tract is ventilated with air and the stomach is emptied until the Flagg test is negative both at the field of operation and the atmosphere adjoining the cautery apparatus at any of its parts

TABLE II — SUMMARY OF 55 CASES

Agent	Total no of cases	Cautery or flame used near head neck chest etc.			Cautery or flame used in abdomen or elsewhere		
		No of cases	Death†	Injured‡	No of cases	Death†	Injured‡
Ether air	12	3	1	2	2	0	2
Ether-O ₂ (with or without nitrous oxide)	17	7	4	5	5	0	3
Ether air or O ₂	6§	6	5	4	~	0	3
Ethylene	9	1	1	1			
Ether or ethylene or both	1	1	1				
Ethyl chloride	3				3	0	2
Acetylene	3				2	0	2
Cyclopropane	2§						
Alcohol		1	0	1	1	0	1

*The cases counted in this group are only those in which the presence or absence of injury is known
†The total number of persons injured or killed is stated in some instances more than one person was injured In no case was more than one person killed
‡One patient died—classification not possible for want of details of explosion

b If the field of operation is on or in the abdomen, pelvis, perineum, lumbar back, and extremities, the anesthetic may be continued with a closed circuit administration together with the precautions advised in paragraph 4 or the anesthetic may be changed to a noncombustible type with the precautions which are advised in paragraph 6a

In the event of the situations described in either paragraphs 6a or 6b, proper ventilation away from the cautery and toward the head of the patient should be arranged

We realize that these rules of conduct appear complicated, but they really are not any more than a detailed description and summation of modern anesthetic procedure as practiced by many leading anesthesiologists, and required of all who wish to avoid any of the accidents known to have occurred

This description is an elaboration of the knowledge which Guedel assumes when he states the factors determining the use of the cautery in the presence of an inflammable agent as "appreciation of the weight of the vapor, the distance of this from the cautery, the amount of vapor freed into the room and the direction of air currents The only unusual precaution we have added is the Flagg test which should be more widely and frequently employed to substitute proof of safety for guesswork Of course, the simplest and ideal

The respiratory tract of a patient in third stage anesthesia under ethylene-oxygen probably does not contain an explosive mixture because the concentration of ethylene is in the range of 85 to 90 per cent whereas the upper limit of explosive concentrations of ethylene in oxygen is 70.9 per cent (21). Within a few breaths of air or oxygen, however the explosive range is reached. The exhalations of a patient under cyclopropane oxygen are always inflammable just as is true of ether because the anesthesia concentrations are always in the inflammable range. As to how long the respiratory tract contains an inflammable mixture after the cessation of administration of ethylene or cyclopropane there are no definite data but one should apply all the precautions advised here for ether: namely the breathing of fresh air the use of the Flagg test, and intubation of the stomach.

The preceding discussion of facts, which might be of value when the cautery is to be used in or near the head of a patient who has received a combustible anesthetic, should not be interpreted to mean that we believe this to be good practice. When any igniting agent is to be employed in such a dangerous location it is far safer and it is our invariable rule, to use a noncombustible anesthetic technique. But there have been and will be many instances when, after an inflammable anesthetic has been given the surgeon is suddenly and unexpectedly required to use a cautery: fulguration, coagulation, etc. In such circumstances, the information which is given here will prove to be invaluable.

CLINICAL DATA

Most writers flatly object to any use of the cautery in the presence of combustible anesthetics. Others have employed the cautery with only few precautions. For example, Horsley (20) has reported using the cautery in 4 of his first 116 anesthetics with ethylene-oxygen with only partial rebreathing without any trouble although care is always taken to increase the operating room ventilation temporarily while the cautery is being used and the cautery is never used near the mask nor in operations on the head or neck. Yandell Henderson (8) has stated the use of the cautery in the abdomen (with ethylene and partial rebreathing) is safe only when a screen or curtain is placed between it and the patient's face. Personal communications from many surgeons of long experience have described the long and uneventful use of ether by open drop or partial rebreathing administration during cauterization in the abdomen, pelvis, and perineum. It is to be expected that those who practice or allow the

practice of anesthesia with carelessness, or who are ignorant of its hazards are not likely to submit reports to the literature or scientific societies and therefore, just those in greatest need of criticism and correction avoid them.

On one point all authorities are agreed. Under no circumstances can any cautery or other spark producing equipment be used around the head of the patient or the pleural cavity, when the patient has been anesthetized with any inflammable anesthetic. To do so is criminal negligence (20). Despite this unanimity of opinion, we have been able to find in at least 26 of the 55 cases of combustion reported in this paper due to the cautery and flame that the igniting agent was used under conditions which would be considered today to be criminally negligent.

Many authorities realize that it is not practicable to prohibit any and all use of the cautery in the presence of a combustible anesthetic (27, 30). A large number of leading anesthesiologists have admitted using cyclopropane, ethylene, or ether by closed circuit administration during the application of a cautery in abdominal operative procedures (5).

It is imperative that we formulate what we consider a safe and practicable set of principles governing the use of the cautery in the operating room. After a study of the physical and chemical data the published and unpublished reports of others and as a result of his own experiences, observations, and discussions with leading anesthesiologists, the writer has formed the following opinion:

1 The anesthetist should specifically inquire before the start of the anesthesia as to the possible use of the cautery.

If the cautery must be used on or in the head, neck, shoulder, chest, respiratory passages or pleural cavity the anesthetic must be of a noncombustible type (e.g. regional block, nitrous oxide intra-earous barbiturate or rectal basal anesthesia or combinations of two or more of these). The use of chloroform is to be avoided because it is decomposed by heat to form irritating fumes (30).

3 If the cautery must be used in the abdomen, pelvis, perineum, lumbar back, lower extremities or distal parts of the upper extremities, the anesthetic of choice should be of a noncombustible type provided it is as safe, from all other viewpoints, for the patient as would be the combustible inhalation anesthetic that would have been chosen had the surgeon not used the cautery.

4 If the cautery must be used in those regions listed in paragraph 3 and a combustible anesthetic must be administered because of the condition of

precaution against explosions is to avoid all combustible anesthetics when the cautery or flame must be used in the operating room. The more experienced and versatile the anesthetist the more often is the ideal precaution practiced. But we must remember that many circumstances associated with the surgeon, patient, or anesthetist prevent the use of a noncombustible anesthetic everywhere and every time a cautery is employed.

CASE REPORTS

We possess the records of 55 cases of anesthetic ignition by a cautery flame, or similar hot object (Table II). These include all that were obtained by circularizing the members of the American Society of Anesthetists and by intensive searching of the literature. They are only a small fraction of the total number of such accidents of which the very great majority have remained untold for fear of criticism or litigation.

SUMMARY AND CONCLUSIONS

In this paper the second of a series of reports on anesthetic combustion hazards, we have presented the physical, chemical and clinical data required for an adequate understanding of the dangers and the safeguards associated with the presence of a cautery or flame in the operating room.

1. Fifty-five anesthetic (and related) fires and explosions ignited by a cautery or flame have been collected. These are all the cases we could find after a survey of the literature and extensive questioning of members of The American Society of Anesthetists, Inc.

3. In at least 26 cases, the cautery or flame was present in or near the head, neck, chest, and respiratory tract of the patient and in all of the other cases the cautery or flame was incorrectly or inadequately protected from contact with a combustible agent.

4. In no instance was there a really closed circuit of administration although in several instances there were attempts to secure complete rebreathing for carbonization about the head and the anesthetists involved believed the circuits to be tightly closed.

5. Tabulation of the 55 cases presented in this report clearly shows the truth of the following statements:

a. Explosions and fires of all combustible anesthetic agents and mixtures are capable of causing death.

b. Explosions of ether-air mixtures are capable of causing death.

c. Ether-air mixtures have a relatively small tendency toward propagating a wave of flame or pressure into and down the respiratory tract.

d. Ether-oxygen, with or without nitrous oxide, has the same great tendency toward propagating a wave of flame or pressure through the respiratory tract as has ethylene-oxygen and cyclopropane oxygen when compared under similar clinical circumstances, i.e., the location of the point of ignition with reference to the respiratory tract of the patient.

e. In no case of which we have satisfactory knowledge has anyone been killed when the cautery or flame was present outside of a 12 inch zone surrounding the upper respiratory tract. This is just as true of ethylene as it is of ether. The large admixture of air (79 per cent nitrogen) which is inevitable when the inhalant anesthetic is ignited at a distance of 12 inches or more markedly diminishes the great explosive force and propagation tendency of combustible mixtures containing high oxygen percentages.

f. All deaths—and all were patients—have been the result of a flame or cautery employed within a 12-inch danger zone surrounding the upper respiratory tract.

6. The Flagg test for the determination of the combustible nature of the atmosphere over or in a proposed field of use of the cautery has been described and recommended.

7. A set of rules for the use of the cautery in relation to combustible anesthetics has been outlined and proposed for the standardization of safe practice.

8. If the cautery must be used in or near the head, neck, shoulders, chest, and proximal parts of the upper extremities, the anesthetic agent must be noncombustible.

9. If the cautery must be used in other parts of the body or operating room the anesthetic agent of choice should be noncombustible. If it must be combustible then the safeguards described should be followed to the smallest detail.

10. The cause of anesthetic explosions and fires when ignited by a cautery or flame is ignorance or carelessness. The prevention depends entirely on education and the elevation of the standards of anesthetic training and practice.

be carried out as for carcinoma situated at a higher level. Carcinoma of the cardiac end of the stomach may also be resected through the same approach and esophagogastronomy performed. The left chest is opened preferably through the eighth rib bed, and the lower esophagus including the accompanying vagi, isolated. The phrenic nerve is pinched, and the diaphragm is opened back to the esophageal hiatus. The lesser curvature of the stomach is ligated off down to and including the gastric artery, and the greater curvature is freed to a variable extent depending on the situation of the carcinoma. If it is in the esophagus and high enough to permit, the esophagus is divided at the cardia and the distal end is invaginated, if it extends to the cardia the division is made through the adjacent stomach and the distal end turned in. If the tumor is primary in the cardiac end of the stomach, the greater curvature should be ligated off along at least its upper half and the spleen removed. The stomach is then transected well below the tumor and the distal cut end is closed. Anastomosis is then made whether after resection of lower esophagus only or of upper stomach and lower end of esophagus by approximation and suture of end of esophagus to side of stomach within the chest. The diaphragm is sutured about stomach and the chest wall is closed tightly with an intercostal mushroom catheter inserted for suction drainage.

The writer has had a personal experience with nine resections: six primary in the esophagus and three primary in the stomach. Of the six primary esophageal cases, four patients survived the operation and of the three primary gastric cases two patients survived. Of the four cases of esophageal resection through the thorax and neck one patient died eight days after operation, one is alive after seven months and two died of recurrences ten

and fourteen months, respectively, after operation. Of the five cases—two esophageal and three gastric—treated by resection and esophago-gastrostomy, one patient, an esophageal case, is alive and free from signs of recurrence three years and five months after operation and of two gastric cases both survived the operation but have been operated on too recently to judge about the likelihood of recurrence. One patient with esophageal infection as a result of the operation and one with gastric resection died from local

There is every indication that transthoracic resection will soon become the recognized form of treatment for carcinoma of the thoracic esophagus and of the cardiac end of the stomach and with early diagnosis and early operation, the results should equal those obtained in surgery for carcinoma of many other regions of the body.

DALLAS B. PHEMISTER

MYOMECTOMY

BECAUSE myomectomy is an inherently more difficult operation than hysterectomy, its performance by any but experienced gynecologists is often associated with a higher mortality. As a result, it is still generally believed to be the same dangerous operation which, like hysterectomy, it was when it was first introduced. As a further result, its present field of usefulness is deliberately limited, although actually, when comparative series are reported by the same competent surgeons, the mortality of myomectomy is no higher and is frequently lower than that of hysterectomy.

To justify its performance, the end-results of myomectomy must include anatomical restoration, symptomatic relief and functional cure. To achieve these results, a very careful selection of cases is necessary.

RESECTION FOR CARCINOMA OF ESOPHAGUS

THE progress that has been made in the operative treatment of carcinoma of the esophagus and of the cardiac end of stomach involving esophagus represents one of the most rapid and striking contributions to surgery in the past four or five years. For about thirty years previously numerous attempts had been made at resection of the esophagus. The percentage of survivals following operation, however was small and early recurrence was the rule, although the first case to be successfully resected by Torek in 1913 was free from recurrences at the time of death thirteen years later. In 1938 Garlock reported three survivals following thoracocervical resection and Marshall and Adams and the writer reported one case each of survival following transthoracic resection and esophagogastrostomy. Then began a sharp improvement in results, and a veritable wave of operating is now sweeping over the surgical centers of the country. That the un-

dertaking is a justifiable one is indicated by the reports of the *Transactions of the American Association for Thoracic Surgery* for 1941 and of Garlock.

The advancement has come about as a result of better anesthesia, better control of intrapulmonary pressure, more liberal use of blood transfusion for maintenance of the circulation and respiration, and better technique of esophagogastric anastomosis based partly on animal experiments and partly on experience in human operations.

Resection for carcinoma of the upper half of the intrathoracic esophagus may be performed through either the left chest after the method of Torek and Garlock or through the right chest after ligation of the vena azygos as advocated by Wookey. In either case the proximal portion of the esophagus is brought out through the neck and an esophagostomy established as low on the neck or chest as possible. If there is sufficient esophagus left at the lower end an esophagostomy is performed by making a short abdominal incision just below the xiphoid, passing a dressing forceps backward above the left lobe of the liver through the esophageal hiatus, grasping the pursestring suture of the esophageal stump and pulling it through to the surface. If inferior esophagostomy is impossible a large mushroom catheter gastrostomy may be performed. Reconstruction of the esophagus by a tube of skin from the front of the chest has been carried out by Wookey.

For operable carcinoma situated in the lower esophagus left transthoracic resection followed by esophagogastrostomy is usually feasible, but, when approximation and anastomosis cannot be attained the operation should

EDITORIALS

higher percentage of malpositions and dystocias than occur in other pregnancies in the same age groups, and cesarean section need be performed only on absolute indications, since the myomectomy scar is somewhat less liable to rupture than the cesarean section scar.

Attention to certain technical considerations simplifies the operation and makes it more likely to produce the desired results. Preliminary curettage should be carried out routinely, to remove polyps, identify possible submucous fibroids, and rule out possible malignant processes. Absolute hemostasis is essential. It can be secured by a variety of simple devices, such as preliminary control of the uterine blood supply, and the placing of additional sutures half an inch beyond each end of each individual incision into the uterus. Care should be taken that sutures are not tied tightly enough to blanch the tissues, which would lead to ischemia and sloughing.

Judgment is required to determine whether multiple incisions or the removal of several fibroids through a single strategically placed incision is the wiser. Incisions on the posterior uterine wall should be avoided whenever possible, and careful peritonealization should be carried out if they must be employed.

There is almost no contraindication to the opening of the uterine cavity, even during pregnancy, when, if complications should develop, myomectomy can usually be performed without disturbance of the gestation.

There can be no quarrel with Victor Bonney's statement that since cure without deformity or loss of function must ever be surgery's highest ideal, myomectomy is a higher surgical achievement than hysterectomy for the inexperienced gynecologist, if for no other reason than that there is no standardized technique for its performance, as there is for hysterectomy, and the method of procedure therefore depends upon the exigencies of the individual case. Naturally, this is no contraindication to myomectomy. The patient's indisputable right to the best possible treatment for her special trouble should not be dependent upon the inability of her gynecologist to perform a certain operation because it is difficult, or his ability to perform one operation, particularly one which is mutilating in its results, better than he can perform another, particularly another operation which preserves function.

HILLIARD EVE MILLER

The single myoma is the ideal type for myomectomy although all types and combinations of types, including the submucous variety can safely be removed. Although a hundred or more tumors have been successfully removed from the same uterus, hysterectomy in such circumstances would usually be the operation of choice. Subsequent childbearing being one of the prime objects of myomectomy there is small point to the preservation of an organ the musculature of which is so damaged that pregnancy is unlikely to occur in it. Quite aside from the size and number of growths they frequently present, myomectomy is usually contraindicated in negro women because the high incidence of associated adnexal disease in this race militates against the functional result which is one of the aims of the operation. By similar reasoning, the location of myomas in the uterine horns is another contraindication to myomectomy. Pregnancy can occur after the removal of one tube and the opposite ovary or even after such ordinarily undesirable procedures as bilateral resection of the ovaries, but the majority of gynecologists doubt that plastic procedures on the resected tube are ever of great value. Degenerative changes, being usually limited to the tumor itself are not a contraindication.

The ideal age for the performance of myomectomy is from 25 to 38 years. Below that period fibroids seldom cause symptoms, and over it the preservation of function is not of great importance. The upper age limit may occasionally be exceeded if a single fibroid is found in an otherwise healthy pelvis, in the course of surgery for other conditions or if the patient insists for some reason upon the preservation of the uterus.

If these various limitations are observed myomectomy will be found applicable to perhaps 10 or 15 per cent of all the patients with

uterine fibroids seen in private practice. Proportions as high as 25 to 50 per cent, which have been reported, suggest that the indications have been unduly exceeded. For economic or other reasons the operation is seldom possible or even desirable in patients seen in public institutions.

Recurrence of the tumors is a possibility in a small proportion of cases 3 per cent is a conservative average, though higher percentages are occasionally reported. Recurrence is unlikely after the enucleation of large single tumors and most frequent after the removal of multiple small "seedling" tumors, for which, except for special reasons, myomectomy is not usually a very wise choice. The patient for whom myomectomy is proposed should always be warned of the possibility of recurrence but may with equal fairness, be told that it is unlikely.

Anatomical restoration of the uterus can usually be anticipated, the process of involution reducing it to normal size and shape within 2 or 3 months after operation, even when immediately afterward it is large and its contour is irregular. Symptomatic relief that is the correction of dysmenorrhea and the return of the periods to normal in character frequency and amount of flow can be looked for within the same length of time in 80 per cent or more of all cases.

Myomectomy should not be undertaken for the relief of sterility until the problem has been surveyed from every possible angle and the candidate for operation should understand that no definite promises can be made as to results. The reported successes, however run as high as 33.3 per cent when the basis of computation is the number of suitable subjects, and when due allowance is made for the not inconsiderable number of women who frankly do not desire children. Subsequent pregnancies are associated with no

is a testimonial to its worth. It is unfortunate that one of the authors, Dr Howard Ruggles, whose untimely death occurred on December 29, 1930, could not help in the preparation of this sixth edition.

The general character of the book has not been changed nor has any attempt been made to cover the entire subject completely. The subject material is presented in a concise but adequate manner and covers the entire field of roentgen diagnosis. The more recent advances in roentgen interpretation have been described and illustrated. In many instances illustrations have been replaced and new ones have been added. The only possible criticism that one could make is that the illustrations are in the positive rather than in the negative phase. This book is recommended without reservation as a text for undergraduate students, to postgraduate students in radiology, and to the medical practitioner.

CARL F. BARTH

THE third edition of Kolmer and Boerner's *Approved Laboratory Technic*¹ is practically the same as the second edition except for the addition at the end of the book of an appendix of the newer methods developed in the last few years. These methods include the Donath Landsteiner test for paroxysmal hemoglobinuria, Quick's method for quantitative determination of prothrombin, methods for the examination of semen, Sparkman's methods for urobilinogen in feces and urine used as a liver function test, Quick's method for hippuric acid in urine for liver function, Cherry and Crandall's method for serum lipase for pancreatic disease, a simplified Kolmer complement fixation test to be used in laboratories doing large numbers of tests for syphilis, the Eagle modification of the Wassermann test, a modified Medes method for vitamin C in urine and the Farmer and Abt method for plasma, the Bratton and Marshall methods for sulfanilamide in blood and urine, and sulfathiazole in blood, the bedside method of Ratish and Bullock for sulfapyridine in blood, and Barker's method for thiocyanates in blood. The only changes in the main portion of the text from the last edition are the correction of errors and the addition of two tables: one, on page 314, is by Merritt and Fremont Smith comparing normal cerebrospinal fluid with blood plasma, the other, on page 370, tabulates the color changes of the indicators of Clark, Lubs, and Cohen.

In most instances only one method is enumerated for each test, on the whole these are adequate. A uniform method of presentation of each test is conformed to throughout the book. The principle of the test is stated first, then the technique is given in outline form making it easy to follow. A praiseworthy feature in many of the procedures is the statement of the sources of error. A large number of the methods have a brief discussion of the interpretation or sig-

nificance of the results of the test. However, this is not adequate to make this volume valuable as a textbook for medical students.

The authors have been assisted by 28 collaborators, all of whom are outstanding in their particular field.

This excellent volume on laboratory technique has been brought up to date by the addition of all the important new tests. It excels particularly in the two sections devoted to bacteriological, mycological and parasitological methods and serological methods. These two sections comprise 372 of the 870 pages. There are 380 figures in black and white and 12 colored plates. Fifty pages of index make reference easy. As a laboratory guide and reference book, it should be available to every clinical pathologist and laboratory technician.

OPAL HEPLER

SINCE there is no preface or foreword to *Fractures* by George Perkins², it is difficult to estimate the scope of the author's purpose. This book is a comparatively small one of 381 pages with a brief and perhaps inadequate index. It is written in a crisp, staccato style, and is almost outline in form. The illustrations are for the most part stippled line drawings, giving an elementary appearance far too diagrammatic to be useful to the student, as they in no way depict the contiguous soft parts which so often play a leading role in the management of fractures.

In many instances there are incomplete pages and the work as a whole cannot be taken as a good example of the bookmaker's art. It is entirely possible that this is due to the conditions under which it was published in London, 1940.

This book cannot be recommended for either student or practitioner as a textbook on fractures. It is essentially a handbook and will answer in a cursory way most fracture problems. Reading the book is analogous to attending a concentrated refresher course in fractures, and, as such, it may prove a useful adjunct to libraries of practitioners who may not have the time or facilities to go more deeply into a given subject in this field.

J. K. STACK

THE book by Griffith and Mitchell, *The Diseases of Infants and Children* has been revised and published under the title, *Textbook of Pediatrics*³. The authors have condensed and attempted to simplify the book so as to be more valuable for student use. The revised book is a compilation of the knowledge of over 60 authorities in various fields. However, in order to retain uniformity throughout the book, the authors have written the entire work, holding closely to their plan of condensation and readability.

Under the section on growth and development it is good to note that a knowledge of normal variations is stressed. This is especially valuable in pediatrics, a field in which preventive medicine is predominantly practiced.

¹FRACTURES. By George Perkins. M.C. M.Ch. (Oxon.) F.R.C.S. London and New York: Oxford University Press, 1940.

²APPROVED LABORATORY TECHNIC. CLINICAL PATHOLOGICAL, BACTERIOLOGICAL, MYCOLOGICAL, PARASITOLOGICAL, SEROLOGICAL, BIOCHEMICAL AND HISTOLOGICAL. By John A. Kolmer M.S. M.D. Dr. P.H. Sc.D. LL.D. L.H.D. F.A.C.P. and Fred Boerner V.M.D. 3d ed. New York: D. Appleton Century Co. Inc. 1941.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE excellent comprehensive book *Radiologic Physics*¹ is an outgrowth from the authors' experience in teaching the radiation courses at the University of Pennsylvania. At first glance the text appears formidable, but a further study shows that the mathematical considerations have been reduced to minimum and proceed from elementary considerations into the more advanced material. Basic and fundamental information in theoretical and applied electrical engineering and radiation physics is treated in a simple, clear and accurate manner. The book is divided into two parts. The first part consists of a discussion of the theory and practice of electrical engineering as applied to radiological apparatus. The second part deals with the theory and application of x-ray physics to x-ray diagnosis and therapy and to γ-ray therapy. To aid the reader in the mathematical consideration the authors have added an appendix which consists of a discussion of elementary trigonometry and calculus. This book is carefully organized so that it leads the beginner with very little knowledge of mathematics or physics to a firm foundation in the fundamentals of radiologic physics. There has been a real need for a textbook covering these phases of radiology. This volume deserves wide distribution and represents the most thorough discussion of radiologic physics available. It will be of particular interest to radiologists, teachers and students of radiology, but should be of interest to any physician who is interested in the use of electromedical equipment.

EARL E. BAXTE.

AS supervising editor of the *Supplement of The Practitioner's Library of Medicine and Surgery*² Dr. George Blumberg states "There is probably no subject in which change takes place more rapidly than it does in medicine. The publishers feel in presenting this supplement that it covers important new work and brings up to date the entire system."

The first chapter on psychosomatic medicine is followed by one on neutron rays and artificial radioactivity by the recent Nobel Prize winner, John Lawrence. Full sections on chemotherapy and the vitamins are discussed in relation to their various forms by well known authors. Equine encephalitis, torulus, rick titosis, pneumonia and pneumonitis are discussed as well as less familiar diseases such as Bejel and Letterer-Siwe disease.

Some sections are weak, largely because the subject is weak. The sections on therapy are well dis-

cussed, serum therapy in pneumonia, the use of vitamin K, sex hormones, dental caries, surgical relief of pain, surgery of patent ductus arteriosus are a few examples. The timely sections on the drug treatment of mental states and the chemistry and treatment of hypoparathyroidism are sections especially well handled. Many young authors are selected because of their subject interest. On the whole, I think this supplement is very well done.

M. HERBERT BAXTER.

THE second edition of *The Management of Obstetric Difficulties*³ by Paul Titus has been enlarged by the addition of 75 new illustrations and 85 pages of text. The chapter on the causes and treatment of sterility is complete, well illustrated, and of much practical value. Solifluamide and other new medical agents are discussed in the treatment of sepsis.

Old and modern classifications of deformed pelvis are given, and the technique of x-ray pelvimetry by the methods of Thoms and Caldwell and Mayo are described in detail. The practical viewpoint of the author is indicated by his recognition of the necessity of considering the size of the fetal head in the problem of the diagnosis of cephalopelvic disproportion. Apparently, however, he is not familiar with the usefulness and wide application of the simple method of measuring the pelvis with the head. The procedures recommended, with which there might be disagreement, are few and mostly unimportant. In such a practical book, however, the danger of extraction of the breech before the cervix is dilated, following Braxton Hicks' version, should at least have been mentioned if not emphasized.

The text is well illustrated and includes a number of colored plates. One of which is an excellent picture of positive pregnancy test in rabbit.

This text is the kind of book which a doctor can turn for good advice on any obstetrical problem. The author avoids the discussion of controversial points and, on the basis of a generally sound obstetrical doctrine, gives the methods he has selected to be used in each condition. The man in general practice will find the book of much practical use for reference in any obstetric difficulty and a valuable addition to his library.

D. VAN S. HAZEN.

THE popular book *Roadmap to Interpretation*⁴ by Holmes and Ruggles has long since established itself as an excellent textbook for undergraduate. The fact that this is the sixth edition of this classic

THE MANAGEMENT OF OBSTETRIC DIFFICULTIES. By Paul Titus, M.D., ed. W. B. Saunders Co. 1944.

ROADMAP TO INTERPRETATION. By George W. Holmes, M.D., and Howard E. Ruggles, M.D., 6th ed. Philadelphia, Lea Febiger, 1941.

¹RADIOLOGIC PHYSICS. By Charles Wray, E. Reid Warren, Jr., and DuRoi O'Neill, with foreword by Eugene P. Vandergrift, M.D. Springfield, Ill. and Baltimore, Md.: Charles C. Thomas, 1943.
²THE PRACTITIONER'S LIBRARY OF MEDICINE AND SURGERY. Supplement. New York and London: D. Appleton Century Co., 1944.

Many of the changes and reorganization in this book were necessitated by recent and newer knowledge. For example the chapter on vitamins is briefly summarized and brought up to date. The chapter on endocrinology has been modernized. The discussion of the thymus gland is shortened and made more clear and concise. The same change has been made in the discussion of the adrenal gland. The section on treatment gives a brief but usable dissertation on the new drugs and their uses.

Several new chapters have been added. There is a section on pediatric institutions and organizations.

This chapter is short and may give the student and beginner an insight into hospital organization. If so, it has served its purpose.

Following the section on physical growth and development is a new chapter on mental and emotional development. This section correlates the mental and emotional development with the physical and environmental factors.

It can be said without reservation that the authors in this instance have far surpassed their former efforts in forming a "Textbook of Pediatrics."

NUMBER 2A

AMERICAN SURGERY IN A CHANGING WORLD

EVARTS A GRAHAM, M D, F A C S, St Louis, Missouri

IN the slow, painful progress of human culture and advancement there have been frequent interludes in which this movement has been stopped temporarily by the catastrophe of war. For a thousand years, however, no threat of an extinction of culture and of the finer qualities of our civilization has arisen equal to that which exists now in the appalling possibility of a victory of Hitler and of his Nazi barbarians. It seems fitting, therefore, that at the meeting this year of this great body of surgeons we should consider soberly some of the consequences upon our profession which the war may have, particularly in order that by thinking of them now we may perhaps be better prepared to prevent their occurrence.

It is almost incredible that the Germany of only fifty years ago in which there originated much of the groundwork of modern science, including many of the important developments of surgery, should have degenerated into its present position of practical denial of the true values of intellectual enterprise.

The Nazi philosophy of the supremacy of brute force can hardly be reconciled with the fundamental ethical principle of attempting to help the weak and the underprivileged patient which has always been the basis, and, may I say the glory, of medical practice at least

during the Christian era. Shirer,¹ in his *Berlin Diary* states that on May 6, 1940, Bernhard Rust, Nazi minister of education, said in a radio broadcast, "God created the world as a place for work and battle. Whoever doesn't understand the laws of life's battles will be counted out, as in the boxing ring. All the good things on this earth are trophy cups. The strong win them. The weak lose them." This authoritative statement from the man in charge of education in the Germany of today and possibly of continental Europe tomorrow, if taken at its face value, can mean only that in his opinion the purpose of education is to enable the strong to become stronger in order better to rob the weak. Surely that cannot be, some will say. It is unthinkable that anyone in a responsible position of authority could subscribe to so bestial a philosophy. But is not a sufficient answer to that complacent doubt to be found in what has already happened in the countries reduced to slavery—Poland, Czechoslovakia, Denmark, France, Norway?

Let anyone picture to himself the consequences if this conception of the ideals of education should dominate the world. In medicine no more humanitarian principles! Gone the charity hospitals! No more bother about crippled children! It is their own misfortune if the poor are sick and the children are crippled.

Presidential address of the retiring president presented before the Clinical Congress of the American College of Surgeons Boston November 3-7 1941

¹Shirer William L. *Berlin Diary* p. 328 New York Alfred A. Knopf

They are the weaklings. They 'will be counted out, as in the boxing ring. What of the effect of the glorification of such brutality upon the doctor himself and especially upon the surgeon? Is such a philosophy compatible with the kind of surgical practice with which you and I are familiar? Certainly not. Why carry out all the troublesome details to make an operation as safe as possible? If the patient is strong he will recover anyway and why worry if the weak does not survive? Doubtless the extreme results on the practice of surgery which I have just mentioned would not occur quickly but in the long run the corroding influence of a philosophy of brute force accepted by the dominant people of the European continent would be bound to degrade the present high standards which have been set up.

If then at the conclusion of this war Nazi influence should dominate the world a recurrence of the Dark Ages would seem to be inevitable so far as education and the progress of science is concerned. The spirit of the Spanish Inquisition would rear its ugly head again. Has it not already done so in those regions which have come under Hitler's control? The atmosphere of freedom necessary for the growth of science and the spread of education would not exist. German surgery since Hitler came to power has been practically sterile.

Those in America who because of the wide expanse of the Atlantic Ocean feel secure against the possibility of a successful Nazi military invasion may think that it is of little concern to us here whether or not Europe adopts the Nazi ideology. But I cannot agree with that opinion. It is admitted probably by everybody that if Hitler is victorious in the European conflict it will be necessary for the United States to remain on a war footing indefinitely. This will mean not only a large army and navy but large taxes also. We have become accustomed to depend on private benefactions for much of the support of our universities and hospitals. It is common knowledge, frequently expressed, that already the reduction of private contributions has seriously handicapped many of our institutions. If those contributions become still less because of higher and higher taxes for the support of a huge preparedness program, radical changes

in the whole scheme of higher education and of the support of scientific research will probably be necessary. It seems hardly possible that either education or research would be supported on the same generous scale if that support were dependent largely on government grants. Certainly much of the freedom to which we have long been accustomed in the privately supported institution would be curtailed with all the restraints, delays, and red tape necessitated by dealing with government clerks.

More important though might be the spread of the demoralizing Nazi theories of education to this side of the Atlantic which might be accepted under the impulse of necessity in competition even if they were considered undesirable. As long as three years ago reports from Germany indicated that the medical course had been shortened by a year and a half because of the demand for more medical officers in the Army. Is it inconceivable that such pressure might be made in this country for a shorter and more practical training if we are forced to stay indefinitely on a war basis? The close integration of the world which has been brought about by modern transportation and communication has made it difficult even for an educational system of one country to be uninfluenced by that of another strong and dominating nation.

That science knows no political boundaries is a common remark. An idea expressed in one country is elaborated in a second and built upon in a third to emerge as something practical and perhaps utilitarian. Great accomplishments are necessarily the products of many minds and hands. Surgical science in its development has been no exception to this rule. The evolution of modern surgery has been the work of all the enlightened peoples of the world, and the chief contributions to it have been made by those who have lived in atmospheres of the greatest intellectual freedom. If Europe continues to live in slavery and the rest of the world becomes an armed camp there will be little prospect of any notable advance in any of the sciences or cultural activities even on this side of the Atlantic.

At a time like this when international hatreds are strongly aroused it is well to recall some of the epoch-making contributions which

have served to create our modern surgery. Although it is difficult, if not impossible, to date the beginning of any great movement, to say who actually started it, it seems reasonable to state that the birth of the modern scientific spirit of surgery can be traced more definitely to the immortal Englishman, John Hunter, than to any other individual. Before his time, and for that matter during his life (1729-1793), there was no experimental approach to surgical problems and no accurate knowledge of the pathological conditions present. Surgical operations for the most part consisted of amputations, the opening of abscesses, and the removal of superficial tumors. Hunter, however, by his resort to the experimental method, his careful study of pathological specimens, his observations on comparative anatomy and embryology established a scientific basis without which the surgery of the present day could not have developed. While Hunter was inaugurating the new sciences of experimental pathology and experimental surgery in England the army surgeon in Germany, according to Garrison, was still being called *Feldscherer*, because it was his duty to shave the officers.

To Great Britain, of course, also must go the credit of creating the antiseptic principle in surgery, carried to a revolutionary success by Lister, but later modified by the German, on Bergmann, into the technique of the present day asepsis. Lister's discovery, as everyone knows, made it possible for the first time to perform an operation on a patient without the previous fear of wound infection. The tremendous practical value of that work is likely to overshadow its other aspects. To me, however, some of those other aspects are of the greatest importance. Lister was a man of the same mental stripe as John Hunter. He was both a logical thinker and an experimentalist. From experiments which ran over a period of about twelve years he reached certain tantalizing conclusions about the nature of wound infection but he was unable to go further on his own knowledge. For example he had concluded that (1) putrefaction caused suppuration, and wound infection did not occur without suppuration, (2) suppuration (decomposition) was in some manner caused by the presence of air, (3) the gases in the air

were not responsible. What could it be in the air that was responsible, if not the gases? In 1865 his colleague at the University of Glasgow, Dr. Thomas Anderson, the professor of chemistry, called his attention to the papers of Pasteur on fermentation and putrefaction. Now he found the answer to his question. This to my mind is a splendid example not only of the interdependence of one nation upon another in science but of the interdependence of one science upon another. Was it not a revolutionary idea in itself at the time that a surgeon could receive help from a chemist on a "practical" problem like the healing of a wound?

Another major British contribution to the development of modern surgery has been the part played by the trained nurse. It seems doubtful to me that the art of surgery could have reached its present high plane without the sympathetic devotion to the patient and the careful attention to details which can be given only by intelligent women. The fact that Florence Nightingale and Joseph Lister were contemporaries has been of the greatest importance to us.

Germany through the influence of its great universities on medicine during especially the latter half of the nineteenth century and in the present century until the World War did much to extend the development of the scientific spirit in surgery. The older members of this audience will recall how eagerly the German surgical journals were read before the World War to learn of the latest developments in both the art and science of our profession and with what authority we at least in this country considered the German masters to speak. In looking back now, however, to the period nearly thirty years ago when German surgery was at its peak it would seem that what inspired us and fascinated us most was the spirit of scientific inquiry which was developed in that country to a greater degree than in any other up to that time. The best German university surgical clinics were centers of experimental investigation and were influenced by, at the same time as they themselves were influencing, other medical sciences, notably physiology and pathology. With the advent of antiseptic and aseptic surgery the German and

Our own surgery more closely resembles that of the British than any other. The differences are somewhat intangible and difficult to describe yet they are apparent. They can perhaps best be summarized by stating that we are more theoretical and less practically minded. We are a younger nation and, therefore, less conservative. The British surgeon is a master clinician in the application of the older art of physical examination to diagnosis and he is unexcelled in technical operative skill. He has carried on splendidly the tradition of anatomy as the foundation stone of surgery. We Americans, on the other hand as a result of the changes in our undergraduate medical curriculum, have almost forsaken the gods of our fathers, anatomy and pathology. We have been seduced by the newer and more alluring gods of physiology and biochemistry. We have become more interested in function than in structure. It has been an amazing revelation to the American Board of Surgery to find that a generation of young surgeons has grown up whose ignorance of the anatomy and of the pathology of the structures with which they are dealing is abysmal. The wonder is that such men can be doing as good surgery as they undoubtedly are doing. Although the revelation shakes one's faith somewhat in the necessity of a sound knowledge of anatomy and pathology nevertheless, it is difficult to believe that these same men would not be doing much better surgery if they did have sounder knowledge of those subjects.

It is probably an inevitable characteristic of a young rapidly developing nation to become ambitious to equal or to excel the accomplishments of older nations. The spirit of inquiry and of experimental research prevalent in the better German clinics before the First World War found favorable soil on this continent when it was transplanted here by many young men who saw in the rapidly developing sciences of physiology and chemistry many applications to clinical problems. It is not surprising therefore that the stream of publications appearing in the German journals had a profound influence on American surgeons. Moreover this influence came at a time when we in this country were most able to take advantage of it. From the beginning of

this century on, more and more opportunities were presented to young men to undertake original experimental work. After the great awakening and the revolution in medical education which followed the publication of the Flexner report in 1910, together with the work of the Council on Medical Education of the American Medical Association, these opportunities were greatly multiplied. Experimental investigation and the spirit of scientific inquiry became glorified. The older more drab and less fertile disciplines of anatomy and pathology became seemingly of less importance to the ambitious young surgeon. His desire was to startle the world with a new and important discovery. Not much chance of doing that in the intensively cultivated and exhausted soils of anatomy and pathology. The urge to get into print to make his name known obsessed every young surgeon who was ambitious to get along. Positions of prestige and influence were often filled on a basis of the candidate's publications more than on any other qualification. Sometimes the list would be regarded as more imposing if the number of the published articles exceeded those of the rival candidate, without a sufficient regard for their quality. Is it any wonder then that this urge for recognition resulted in a dimming of the lights of anatomy pathology and the old established methods of physical examination of the patient?

One of the American characteristics most frequently noted by foreigners is our tendency to undertake a new project or to accept a new idea with the utmost vigor and enthusiasm. Our acceptance of the value of the spirit of research in medicine was no exception. The movement in this country developed into a veritable surge, and large numbers of young men crowded into the research laboratories to find out something new. The printing presses were overworked to publish the volumes of work produced and scores of new medical journals appeared. There was little excuse for any Milton to be mute and inglorious. It was to be expected that most of the ambitious young investigators would be unfitted by nature to startle the world with any epoch-making discovery. On the other hand some yes even some of the young surgeons, have

made very important fundamental contributions to our knowledge not only of physiology, both normal and abnormal, but even of pathology and of the forsaken subject anatomy, especially the anatomy of the nervous system. Others have added smaller stones to the building of our edifice. The spirit of research overflowed from this country into neighboring countries and back to Europe. With the benefactions of the Rockefeller Foundation distributed throughout the world there was scarcely a civilized country in which the spark of original investigation was not kindled into flame if it existed at all. Never before in the history of the world has there been anything remotely approaching the flood of scientific discoveries which has occurred in the last twenty years. Perhaps there will never be another period like it. In any case there is bound to be a recession of the wave. Almost certainly this recession has already begun. In all those parts of the world touched by the withering hand of Nazism research activities are impossible. England and Russia are handicapped by their struggle for existence. Only the nations of North and South America are so far free to carry on the spirit of research, and one wonders how long can this go on. Historians often have pointed out the wave-like character of the great cultural advances. During a relatively short period of time enormous progress is made, to be followed by a long period of relative inactivity or actual recession. Notable examples are the so-called Age of Pericles, the Alexandrian Period, and the Elizabethan Era. In view of the present chaotic conditions of the world, it would seem to require much optimism to assume that the period of unprecedented scientific advance through which we have just passed will continue with undiminished tempo.

Along with the recent period of enormous research activity there has been an immense improvement in the quality not only of the best but also of the average surgery practiced in this country. Better medical schools, more and better facilities for a long term specialized education of the young surgeon, more widely distributed well equipped hospitals have all had an incalculable effect in making good surgery available for the mass of the popula-

tion. The high standards set for certification by the specialty boards have been a very stimulating influence in keeping the practice of the various surgical specialties on a high level. The development of group practice brought to a remarkable state of efficiency by the Mayo Clinic and emulated by many other clinics has also been a factor in improving surgical practice.

The influence of the American College of Surgeons has carried much weight in improving the average surgical practice throughout the country. Its splendid work in improving the hospitals of the United States and Canada has already been mentioned. Also important have been its recently increased standards of admission to fellowship, the work of its recently appointed committee on graduate education, its official journal, and its annual meetings where the surgeon out of touch with the medical centers of the country can come to learn of the new developments in surgery.

At the meeting this year an innovation in the program was made. The Forum on Fundamental Surgical Problems was created. This symposium of ninety short presentations of experimental work on surgical problems was arranged largely by the efforts of Dr. Owen H. Wangenstein. It can almost certainly be said without fear of denial that never before at any surgical meeting in any country has there been a program presenting so much original work, mostly by younger investigators. It constitutes, therefore, a unique event. Moreover, it represents, it seems to me, one of the chief characteristics of modern American surgery, the spirit of inquiry and the utilization of all the sciences for the solution of surgical problems. It is a characteristic of which we American surgeons can justifiably be proud. It removes surgery from the realm of mere craftsmanship and translates it into a science. It is this experiment of surgery which constitutes the front line of surgery. Does not this program show that the spirit of the immortal John Hunter still survives? His memorable words to Jenner should be recalled, "I think your solution is just, but why think? Why not try the experiment?"

In the foregoing remarks an attempt has been made to emphasize the fact that the de-

velopment of modern surgery has been due to important contributions from several nations but yet that the practice of surgery has certain national characteristics which make it different in different countries. Reasons have been advanced for assuming that the recent unprecedented period of scientific progress is certain to be checked if it has not already been, regardless of the outcome of the war. A Nazi victory however will mean almost certainly for a time a more or less complete destruction of the scientific spirit throughout the world. It has been emphasized that attempts to preserve our present high standards and to carry forward the light of progress will fall most heavily on those of us who live in the Americas, South as well as North.

Let us now briefly consider some of the ways by which these standards can be preserved. I should say that it is of the utmost importance that the surgeons of North America and of Latin America come to know each other better and to develop a spirit of more sympathetic mutual understanding. The surgery that is being practiced in the centers of Latin America is not excelled anywhere and an increasing volume of original work of very high order is being produced. The knowledge of this work has been only slowly diffused in North America because of difficulties in language. Likewise for the same reason our surgery has not been so well known to our southern neighbors as the continental surgery. Would not a regularly meeting Pan American surgical congress with the cooperation of the American College of Surgeons provide a stimulating and helpful influence in preserving and fostering the spirit of surgical progress at least on this side of the Atlantic while Europe is recovering from the disaster of war? By meeting in different countries and at stated times, either annually or less often, there would certainly arise an inspiration from personal contact and from developing friendships and respects among those most actively engaged in the advance and practice of our profession. More of us North Americans would come to possess a knowledge of Spanish and Portuguese and more of the South Americans, English. There would be a freer interchange of medical literature of ideas and of students. The American College of

Surgeons already has a membership of 225 from Latin America. It could well be more nearly representative of all the Americas, both in membership and in its governing bodies, so that truly it would be an all embracing American College of Surgeons, thoroughly international in its point of view and admiration. This suggestion may seem too radical but we must be prepared to make radical moves if we wish to counteract the results of the swiftly moving tragedy in Europe.

In a discussion of the preservation of our highly developed modern surgery it is necessary to touch upon our duties and obligations to the armed forces of our country in a program of preparedness for war. The Army particularly and to a less extent the Navy need more medical officers. We must do all in our power to provide them during the acute emergency. In striving to preserve our programs of training young surgeons we must not hamper the agencies of our government whose defeat would mean the destruction of our national independence. On the other hand, the armed forces should not unnecessarily and ruthlessly interfere with our laboriously developed system of training. Enough of it must be safeguarded to prevent too great a recession from our present standards. I am pleased to say here to the credit of the wisdom of Surgeon General Magee of the Army and of Surgeon General McIntire of the Navy that every effort has been made to interfere as little as possible with the training programs. Possibly a plan may be worked out whereby the young medical officers, after a limited service can be released to finish their periods of training in the civilian hospitals.

Possibly greater dangers to the safety of our resident system will come from the governing bodies of our civilian hospitals when the specter of hard times looms at them. We must, however hold fast to the principle of the system even if some modifications become necessary. We must not forget that surgery is a science as well as an art and must constantly advance. Above all, to be true to our profession, we must remember that the practice of surgery is based on humanitarian principles. Come what may we shall not subscribe to the philosophy of the supremacy of brute force.

ADRENAL CORTICAL TUMORS

The Types of Nonhormonal and Hormonal Tumors

GEORGE F CAHILL, M D, F A C S, MEYER M MELICOW, M D, and
HUGH H DARBY, Ph D, New York, New York

IN 1936, a study of adrenal cortical tumors was presented by a New York group from the Presbyterian Hospital. At that time it was shown that these tumors could be diagnosed by perirenal air insufflation. Attempts were also made to determine the hormones excreted in these cases. It was shown, that in adult females, normal or high amounts of estrogens were excreted in some tumor cases. At the same time Gallagher found that large amounts of androgens were present in the urine of 2 of the adult female cases but his report was not completed in time to be included in the published paper but was incorporated in the reprints. Since then the adrenal gland has been studied by numerous investigators and there has been a clearer understanding of many of its physiological activities. Coincidental with the advances in the knowledge of the function of the normal adrenal there has been much experimental and clinical investigation into its pathological status. Because of the better understanding of the clinical status with reference to adrenal cortical tumors, we believe that the report of a study of the adrenal cortical tumors which have been seen at the Squier Clinic is worthy of presentation.

THE ADRENAL

The mammalian adrenal is actually two glands fused together in development. Each has an essentially different origin, a different type of tissue and with a separate function, but they happen to be enclosed in one enveloping capsule and tissue stroma. Tumors of the adrenal are not frequent. When they arise they can be basically classified as follows:

From the Departments of Urology (J Bentley Squier Clinic) and Biochemistry, College of Physicians and Surgeons, Columbia University.
Presented before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1947.

1 Tumors derived from the various layers of connective tissue, blood vessels, lymphatics, or nerve structures within the gland which are similar to such types of tumors that may occur in any other gland and as such are not peculiar to the adrenal. They occur very rarely in the adrenal. Tumors of these tissues having been reported as occurring in the adrenal are the following: fibroma, lipoma, neuroma, neurofibroma, myoma, osteoma, hemangioma, sarcoma, lymphangioma, and melanoma.

2 Tumors derived from the medulla are ones peculiar to that tissue and are of the ectodermal sympathetic nerve system. They may be of the basic nerve cell, a sympathetic ganglion, or secondly from the sympathetic plexus or paraganglioma, or thirdly from the pheochromocytes. The first two occur more frequently in children and are seen more often than the latter, which occurring mostly in adults are rare.

3 Tumors originating from the adrenal cortex are mesodermal glandular tumors, and cytologically are hyperplasias, adenomas, and carcinomas. Accessory adrenals occur, called Marchand's bodies. These are of cortical tissue and have been described as in the kidney, the perirenal fascia, the retroperitoneal fascia, within the broad ligament, attached to the ovary, or associated with the gonadal testicular tissues. Tumors of these aberrant adrenals have been reported, all of cortical tumor type and, without and with, similar syndromes as are seen with adrenal cortical tumors. Their occurrence is very rare.

THE ADRENAL CORTEX

In a consideration of tumors of the adrenal cortex, it is essential to evaluate the more recent studies upon its embryology and briefly to review the marked advances of the knowledge concerning its biological processes.

EMBRYOLOGY AND HISTOLOGY

The adrenal cortex originates from the mesoderm of the celom epithelium near the genital ridge and because of its proximity to that ridge Grollman has suggested that cells of the latter may be included with the adrenal and that hyperfunction of these cells may be responsible for the phases of reproductive symptomatology in those cases. The cortex during postnatal life gradually forms into three microscopic layers that are completed to the adult cortex, at or about puberty. The development of the inner of these three layers just before puberty has been shown by Miller Deansley and Whitehead to have some connection with the development at that time of the sexual glands and organs, and because of this it was suggested as an "A Zone" of the adrenal. In this latter zone because of his theory of inclusions in the juxtamedullary layer of testicular cells or rests, Grollman preferred to recognize a fourth zone or special androgenic zone.

A better understanding of the development of the adrenal cortex has been furnished by the studies of Mulon, Bogmoloz, Goormaghtigh, Hoerr and Zwemer in that the adrenal cortex apparently continuously grows from without inward. New cells are formed from the spindle-shaped fibroblastic cells under the fibrous capsule, develop through the three layers from without in the zona glomerulosa, zona fasciculosa, and zona reticulosa and during this process elaborate, accumulate, and discharge lipid sterols and then degenerating are absorbed in the reticulosa near the medulla. The secretion is discharged into the capillaries by the mature cells before their degeneration and the process is constant with replacement by new cells.

Under certain phases of hyperactivity there appear larger number of cells undergoing degeneration than is normally seen. This may suggest the possible reason for the widening of the reticulate zone at puberty (Deansley and Miller) the special zone (Grollman) and the appearance of granules in the cells with fuchsinophilic staining affinities as reported by Broster and Vines.

In relation to the appearance of discrete fuchsinophilic granules found in certain adrenals

in females manifesting virilism as reported by Broster and Vines, and Simpson and Joll the recent report of Sudds is interesting. She found that granules are present in 24 per cent of adult male adrenals and 28 per cent of female adrenals. In females the percentage of glands with granules showed a steady increase with age. With the exception of 1 fetus, in no case under 24 years were they apparent. This report is an excellent investigation of a small number of such sections reported in our previous article (Cahill et al.) in which such granules were found in dogs, in adrenals of individuals without virilism and more marked in adrenal cortical tumors with virilism. Sudds concluded that age has some influence on the presence of these granules, but sex plays no part. By inference from Sudds' conclusions, the presence of the increase of these granules in excess may be due to the aging influence of virilism when it occurs, and not that the granules were direct hormones which logically should be the sterols produced by the adrenal cells.

THE PHYSIOLOGY OF THE ADRENAL CORTEX

The adrenal cortex has been definitely established as the elaborator of hormonal substances, some of which are necessary for life maintenance. The hormonal substances have been shown chemically to be steroid lipoids.

Up to 941 over 20 closely related steroid derivatives have been prepared from the normal adrenal cortex. The action of all of these is not fully known. Of the identified steroids is one with the property of male sex hormone (dehydroandrosterone) (Reichstein) a beta kosteroid that differs only in its chemical structure from the testicular male hormone (androsterone) an alpha kosteroid. There has also been identified as secreted by normal adrenals the female sex hormones, estrone (Beall) and progesterone (Beall and Reichstein). Thus normal adrenals have the power to produce both male and female sex hormones. The excretion in the urine of androgens is small in children reaches a normal in adult life and diminishes after 40. It is relatively small in females. Part of these androgens are considered to be derived from the adrenal. The excretion in the urine of estrogens also

occurs in small amounts in normal males, normal amount in normal females, and part of these estrogens are considered to be probably elaborated by the adrenals

Some of the other steroids elaborated by the adrenal cortex have effects on the salt and water metabolism, the permeability of the capillaries, in the regulation of the carbohydrate, fat and protein metabolism, the renal function, the capacity of muscle response, and the resistance to stress. The maintenance of life and health is probably due to a combination of the various activities of these steroids. Of the identified steroids, one, desoxycorticosterone, seems to be most effective in the regulation of salt and water metabolism, in capillary permeability, and in preservation of renal function but has no demonstrable effects upon the carbohydrate metabolism. The properties of others of these steroids are not as yet clarified so that much further investigation apparently is necessary.

From the multitude of experiments reported there are suggestions that the adrenal may be implicated in many other metabolic processes. It has been shown that there is a relationship between the adrenal cortex and the gonadal pituitary system and that hyperactivity of the ovary may partially replace adrenal function (Rogoff and Stewart, Emery and Schwabe). It is of interest to explain the presence in comparative large amounts of vitamin C in the adrenal cells as shown by Szent-Gyorgyi.

PATHOLOGICAL PHYSIOLOGY

Since the adrenal cortex is composed of hormonal secreting cells, there are periods of cell growth or degeneration in which these cells do not elaborate hormones. Hyperplasia of these cells or tumor of these cells will have large numbers of this stage of cell life present without increase of hormones delivered into the capillaries. Again hyperplasia or tumor of the cells in the various stages of elaborating and secreting the steroid hormones will have an abnormal number of these cells present and as a result the secretion into the capillaries of an excess of some or all of the various steroids. Such has been shown to be the result of hyperplasia or tumor in the adrenogenital syndrome in which the excess amount of male hormones

Fig 1 Diagram taken from Zwemer of the development of adrenal cells, showing the differentiation of the long cells from the cortex into the glomerular zone, the fasciculate zone and into the reticulate zone. During this process, they change, accumulate materials, elaborate substances, secrete them, degenerate, and are removed by macrophages and microphages near the medulla.

elaborated by the tumor has its effect upon the secondary sex organs. This has been shown to occur in the masculinization of females both children and adults and in the male maturity in male children (Simpson, Simpson, de Fremery, MacBeth, Gallagher, and Callow).

Hyperplasia or tumor cells at times have apparently elaborated excess amounts of steroids with female hormonal activity. The effect of these excess amounts of hormones may be registered upon the individual so affected. The feminism of a male has been shown to be the result of excess estrogens elaborated by a tumor of the adrenal cortex by Burrows et al, and by Simpson and Joll. There is then the suggestion that the presence of high amounts of estrogens as reported by Frank, from certain adrenal cortical tumors may naturally show no effect upon a female.

Bauer contends that an excess of the hormones which have the regulation of the electrolytes, salt and water metabolism, fat and sugar metabolism, are produced by the adrenal cortex either in the hyperplasia or in the tumors occurring in the syndrome described under many variations as Cushing's syn-

drome. This has been supported by the work of McQuarrie Johnson and Ziegler and by Anderson and Haymaker.

It has been well established that the adrenals can elaborate androgens and estrogens as well as other metabolic hormonal steroids and there is suggestive evidence that the regulation of these secretions is subjected to if not regulated by stimuli from the pituitary. These androgens and estrogens can be present in excess quantities and responsible for symptoms present. They may result from some aberration of normal cortical steroid metabolism or they may be just an increase of normal production. Evidence is present that with some tumors there may be abnormal steroids produced. From such is the report of Butler and Marrison of the steroid with male hormonal properties (pregnane 3 17 20 triol) associated with an adrenal tumor and they definitely established that such a hormone is not excreted by normal man or from a normal or pregnant woman.

In addition it has been shown by Butler and Marrison and by Venning Well and Browne that some patients with virilism and adrenal hyperfunction excreted pregnandiol and believed that this originated from the cells of the pathological adrenal.

CLINICAL CLASSIFICATION OF TUMORS

Up to 1928 it was relatively rare for patients to be seen in the Presbyterian Hospital who suggested adrenal pathology with the exception of the adrenal deficiency in Addison's disease. Since then because of increased knowledge and interest in endocrine diseases, hundreds of patients with symptoms of supposed adrenal disturbance have been admitted to the Squier Clinic. From the large number examined and the different investigations, the conclusion must be drawn that among adrenal syndromes the adrenal cortical tumor occurs infrequently. When it occurs it may be present without any evidence by symptoms that there is any change in the hormonal balance. In others it is accompanied by symptoms which are definitely due to hormonal influences. These symptoms vary according to the hormones secreted, their amount, and to the age and sex of the individual so afflicted.

The clinical groups, on the basis of proved cases may be classified as follows:

1. No recognizable hormonal changes
 - Changes due to excess androgens
 - a. In female child toward adult masculinity
 - b. In female adult toward masculinity
 - c. In male child toward adult masculinity
2. Changes due to excess estrogens
 - a. In adult male toward femininity
3. Changes due to excess androgens and other steroids
 - a. Cushing syndrome with associated sexual changes (mostly in females)
4. Changes due to excess other steroids related to metabolism
 - a. Cushing syndrome without sexual change (in male and female)

TUMORS WITH NO RECOGNIZABLE HORMONAL CHANGES

Tumors of the adrenal cortex have been reported in the literature as occurring without hormonal changes, (Hartung, Miacera, Stevens, Gibson, Loeb, etc.) They are infrequent and have been seen practically only in adults over 30 and have occurred in both sexes. When discovered they have apparently been present for a considerable period of time, first without any symptoms, but later with the complaint of pain in the side on which the tumor is present. Often when diagnosed the tumor was palpable. The deep situation of the adrenal and delay in invading any of the adjacent viscera for a considerable period before recognition allows growth of the tumor often to a large size. The pain is both abdominal and flank, and usually is made worse by exercise. Symptoms of malaise, fatigue and diminution of appetite are often present, especially in the larger tumors.

The following cases are illustrative of this type of tumor:

CASE A.S. Chart No. 6034, Presbyterian Hospital (reported in 1936) a single woman, aged 35 years, was admitted in 1927 complaining of intestinal trouble and pain in the left side for over a year. (Itk occasional fever and weakness. She had missed her last menstrual period. She had a large mass in her left flank and cystoscopy showed that her left kidney was normal but was displaced downward by the mass. Her blood pressure was 55/68. There were no studies of urinary hormonal excretion. A transperitoneal operation removed a large tumor from above her left kidney. With the aid of a postoperative transfusion she made an uneventful recovery. Sec-

tions of the tumor showed a carcinoma of the cortex of the adrenal gland. In some areas there was a differentiation of the tumor with sections having arrangement of cells reminiscent in places of the different areas of the normal adrenal, the zona fasciculata, zona glomerulosa, and the zona reticularis. In other areas there was little or no such differentiation, but cells varying in size and shape and mitosis and infiltration. After 5 months' improvement there was recurrence of abdominal symptoms. While visiting in Nova Scotia she had an abdominal operation and a section of a liver metastasis was sent to us. This resembled the undifferentiated area of the original tumor. She was reported to have died 11 months after operation.

CASE 2 P J R., Chart No 16156, Presbyterian Hospital (reported in 1936), a male, aged 58 years, was admitted in 1915 complaining of shortness of breath for a year, progressive loss of weight and strength, and blood tinged sputum. His right pleura was aspirated and the fluid contained epithelial tumor cells. At autopsy there was found a tumor of his right adrenal cortex with metastases to pericardium, endocardium, lungs, liver, kidneys, and retroperitoneal tissues. He had no hypertension, no fat deposits, no plasma, hair or secondary sexual changes.

CASE 3 S S., Chart No 360795, Presbyterian Hospital, a male, aged 36 years, married and with children, was admitted in 1936 with pain in the left loin and chest for over a year. He had had a double herniotomy, an appendectomy, a tonsillectomy, and a cholecystectomy in the several years before admission. His left loin pain was in periods lasting 4 to 5 days. There was some loss of sexual vigor and with his pain he often had headaches and thought that these came roughly once a month. He was a vigorous male with a well marked normal hair distribution and with normal male genitalia. There was no hypertension. Cystoscopy and pyelograms were normal except that the inner border of the upper pole of the left kidney seemed shadowed by some tissue. A perirenal air insufflation showed a rounded tumor above and anterior to his left kidney. A large soft adrenal tumor, anterior to the anterior capsule of his left kidney was removed with the kidney through a flank incision. The adrenal tumor capsule broke at the time of removal. After an uneventful recovery he was treated with high voltage x-ray. Urinary hormones estimated immediately after removal of the tumor showed a low excretion of both androgens and estrogens (male 4 I U. and female 3 R U. per day).

Sections of the tumor showed that there was an upper small portion of normal adrenal that blended into the neoplastic. In the tumor part, there were collections of cells of unusual size containing enormous nuclei. The cytoplasm was pale, pink, and smooth. Multiple nuclei were present. Mitoses were occasionally seen. In places the tumor cells were much smaller and resembled the renal hypernephromas. Cells containing lipid vacuoles were not frequent. Areas of necrosis and hemorrhage were numerous.

Two years later the patient was readmitted with an abdominal mass which on transperitoneal exploration could not be removed because of its intimate attachment to the cava and aorta. Urinary hormones before operation showed male 15 international units and female 4 rat units, a low male excretion. High voltage x ray was resumed. He was readmitted 6 months subsequent to this with symptoms of general peritonitis. He refused operation, died, and on autopsy a perforation of a sigmoid diverticulum with generalized peritonitis was found. There was a metastatic tumor involving his aortic glands and his vena cava. Although the vena cava was involved, no metastases were found in his lungs.

CASE 4 A portion of a tumor of the adrenal was sent to us by Dr. M. W. Roome of the Department of Surgery, University of Chicago. This was from a male adult who had a large adrenal cortical tumor without any hormonal changes. The operative procedure was corroborated by autopsy. The cellular pathology of Dr. Roome's tumor was somewhat similar to that of Case 3, although the very large cells and nuclei were not as frequent nor did they appear as large. Lipoid vacuolated cells were rare. Mitosis and infiltration were present.

CASE 5 A K., Chart No 652840, Presbyterian Hospital—Service of Dr. A. O. Whipple, a female, aged 50 years, single, was admitted September 1941 with loss of weight and strength for 8 months. Her history was negative except for menopause 12 years previously. Eight months before admission she began to have loss of appetite, weakness, and a gradual loss of 20 pounds. A mass then was seen to appear in her left upper abdomen without pain for the 4 months before admission. Because of a normal blood count and other tests it was thought to be a large spleen and was given x-ray treatments. With this and sunbaths she became darker in her skin. There was no increase in hair anywhere on her body, no changes in her breasts, and no headaches. She had no hypertension. From x-ray studies the mass was thought to be spleen. She was operated upon and a large tumor mass with dilated veins was removed. It was anterior and above the left kidney and was attached to but did not involve the kidney or the normal adrenal above. She made an uneventful recovery. Sections of the tumor showed cells resembling adrenal cells of the various types (similar to our Case 1). Cells with vacuoles were rare. The diagnosis was carcinoma of aberrant adrenal without hormonal symptoms.

Our 4 cases of adrenal cortical tumors, 2 males and 2 females, were all adults as was Dr. Roome's case. In each the tumor had been present for a considerable length of time and had reached a rather large size. Two presented symptoms of recurrent abdominal and flank pain on the side affected. All showed signs of malaise. One case was admitted in

growth of hair on face, and body all resembling the masculine distribution. Acne may occur on face or chest. The voice frequently becomes deeper and masculine in tone which has been explained as a lengthening of the vocal cords.

Changes occur in the secondary sex organs, but this change is a slower one than that seen in the menses and the hair. The younger the individual the more pronounced are the secondary sex changes. The usual sex organ changes are hypertrophy of the clitoris, deepening of the color of the labia, occasionally atrophy of the uterus and atrophy and loss of sensitivity of the ovaries. In young females the breasts may stay undeveloped resembling a boy at puberty. In older women atrophy may occur.

These changes have been shown to be associated with the appearance of excessive amounts of androgens in the urine. The amount of androgens excreted is proportionate to the masculinity changes that have occurred. The amount may be far above that excreted by males. From one of our cases Gallagher reported 480 international units per day and the average value for normal male in his estimation was 40 international units per day. The highest recorded figure has been in the case described by Slot in which the excretion was 2200 international units per liter. The male hormone isolated from the urine in some of these tumor cases has been identified as dehydroisandrosterone.

Among our female adrenal tumor cases with hormonal syndromes, have been 2 in which the only apparent change was that which could be produced by excess androgens.

CASE 6. G. C., Chart No. 443624, Presbyterian Hospital, reported in 1936, aged 6 years, was admitted in 1935 complaining of hair upon the face and body, deep voice, and no menstruation. At the age of 13 she menstruated for 2 periods and then had complete cessation. Her hair became thicker and darker and grew on her face, arms, legs, and body. She sang bass and was troubled with acne. She had grown practically not at all since 13 years of age, but was very active and athletic. There was marked hypertrophy of the clitoris. The blood counts, chemistry, basal metabolic rate, glucose tolerance, and visual field determinations were normal. X-ray film showed fusion of 11 epiphyses. The left kidney was lower than the right and intravenous pyelograms

showed normal anatomical and functioning kidneys. Air insufflation roentgenograms revealed a small right adrenal and a large adrenal tumor mass above the left kidney. She excreted in her urine 8 rat units follicle hormones in 24 hours. Male hormonal excretion was estimated 480 international units in 4 hours. The left adrenal mass was removed through an oblique subcostal transperitoneal approach. Her recovery was uneventful and rapid. Her menses returned in 8 days and have been normal for over 5 years. Her voice gradually registered higher. She has not grown since in height but her figure has become heavier and markedly feminine. The excess hair came off her body most markedly at menstruation, but her facial beard has persisted, but to a lesser degree. Air insufflation roentgenograms of the right adrenal taken a little over a month after the operation showed that that adrenal had hypertrophied. Estimation of her hormonal output 6 months after operation showed that both were in normal range.

Microscopic sections of the tumor showed areas of cells in loose strands arranged in masses and sheets, resembling in some places the reticulate zone and in others the glomerular zone but in most not resembling any particular area. No mitoses were seen but there was an apparent invasion of the capsule, and there were tumor cells in the blood vessels. A few areas of necrosis were present. There were also present numerous cells with vacuoles, which apparently consisted of lipoids.

CASE 7. R. R., Chart No. 57704, Presbyterian Hospital, aged 8 years was seen in 1939 complaining of hair on face and body and lack of menstruation. She had had normal menses from the age of up to 5 months before admission. She then missed a period, which was followed by a scanty period and there had been none since. At the same time hair appeared on her upper lip, chin, cheeks, chest and buttocks. Hair grew long upon her arms and legs and became darker. Her voice deepened. She had no pain or any other symptom. Her figure resembled a young male adult with male hair distribution. There was hypertrophy of the clitoris and slight hypertrophy of the labia. The pelvic organs were normal except for loss of usual ovarian sensitivity. There was no hypertension. The blood counts and the chemistry were normal. Basal metabolic rate, visual field and glucose tolerance tests were normal. X-ray films of skull, chest, and abdomen showed no abnormality. Air insufflation roentgenograms showed an ovoid tumor of the outer portion of the left adrenal. The right adrenal appeared normal. The excretion of male hormone in her urine was approximately 90 international units in 4 hours. During the same period she excreted 33 rat units of female sex hormones. At operation a ovoid tumor of the outer portion of the left adrenal was resected from the inner or normal portion through a left oblique trans-peritoneal approach. She made an uneventful recovery. Her menses returned to normal 1 month after operation.

normal adrenal is visualized, near the side of the body of the 12th thoracic vertebral body

Fig 3 Case 3 Air insufflation x ray film of left adrenal tumor. The ovoid shadow superimposes upon the upper pole of the left kidney and the narrow compressed band of

Microscopic sections of the tumor removed showed a small area of normal adrenal tissue. The remainder was a tumor resembling in portions the glomerular area but mostly either without definite arrangement or in spots resembling the fasciculate and reticulate zones. The cells varied in shape, the nuclei were mostly round, the cytoplasm was granular, and at times sparse. There were no mitoses seen. Vacuolated cells probably containing lipoids were frequent.

Following her operation her breasts increased and the hair became less upon her body. Her voice became higher pitched. In the 6th, 12th, and 18th weeks following operation the excretion of hormones in her urine was 6 international units male hormone and 35 rat units female hormone in 24 hours.

She progressed without change in her menstruation but the hair remained upon her chin and neck. An insufflation air x ray film of her untouched right adrenal, taken in 1940, showed that the lower end had become rounded and wider. In March, 1941, she noticed that her menses had become scantier and that her hair growth was somewhat more vigorous. She was readmitted to the hospital and insufflation air x-ray films were taken showing that the lower end of the right adrenal had become rounded and resembled a tumor. Her excretion of androgens in the urine had again increased above normal.

Fig 4 Drawing representing the tumor, the adrenal, and the kidney in Case 3

growth of hair on face, and body all resembling the masculine distribution. Acne may occur on face or chest. The voice frequently becomes deeper and masculine in tone which has been explained as a lengthening of the vocal cords.

Changes occur in the secondary sex organs but this change is a slower one than that seen in the menses and the hair. The younger the individual the more pronounced are the secondary sex changes. The usual sex organ changes are hypertrophy of the clitoris deepening of the color of the labia, occasionally atrophy of the uterus and atrophy and loss of sensitivity of the ovaries. In young females the breasts may stay undeveloped, resembling a boy at puberty. In older women atrophy may occur.

These changes have been shown to be associated with the appearance of excessive amounts of androgens in the urine. The amount of androgens excreted is proportionate to the masculinity changes that have occurred. The amount may be far above that excreted by males. From one of our cases Gallagher reported 480 international units per day and the average value for normal male in his estimation was 40 international units per day. The highest recorded figure has been in the case described by Slot in which the excretion was 2200 international units per liter. The male hormone isolated from the urine in some of these tumor cases has been identified as dehydroisandrosterone.

Among our female adrenal tumor cases with hormonal syndromes have been 2 in which the only apparent change was that which could be produced by excess androgens.

CASE 6 G.C., Chart No. 445624, Presbyterian Hospital, reported in 1936, aged 6 years was admitted in 1935 complaining of hair upon the face and body, a deep voice and no menstruation. At the age of 13 he menstruated for periods and then had complete cessation. Her hair became thicker and darker and grew on her face, arms, legs, and body. She sang bass and was troubled with acne. She had grown practically not at all since 3 years of age, but was very active and athletic. There was marked hypertrophy of the clitoris. The blood counts, chemistry, basal metabolic rate, glucose tolerance, and visual field determinations were normal. X-ray film showed fusion of all epiphyses. The left kidney was lower than the right and intravenous pyelograms

showed normal anatomical and functioning kidneys. Air insufflation roentgenograms revealed a small right adrenal and a large adrenal tumor mass above the left kidney. She excreted in her urine 8 rat units follicular hormones in 24 hours. Male hormonal excretion was estimated 480 international units in 24 hours. The left adrenal tumor was removed through an oblique subcostal transperitoneal approach. Her recovery was uneventful and rapid. Her menses returned in 8 days and have been normal for over 5 years. Her voice gradually registered higher. She has not grown since in height but her figure has become heavier and markedly feminine. The excess hair came off her body most markedly at menstruation, but her facial beard has persisted but to a less degree. Air insufflation roentgenograms of the right adrenal taken a little over 1 month after the operation showed that that adrenal had hypertrophied. Estimation of her hormonal output 6 months after operation showed that both were in normal range.

Microscopic sections of the tumor showed areas of cells in loose strands arranged in masses and sheets resembling in some places the reticulate zone and in others the glomerular zone but in most not resembling any particular area. No mitoses were seen but there was apparent invasion of the capsule, and there were tumor cells in the blood vessels. A few areas of necrosis were present. There were also present numerous cells with vacuoles, which apparently consisted of lipoids.

CASE 7 R.R., Chart No. 571704, Presbyterian Hospital, aged 8 years was seen in 1939 complaining of hair on face and body and lack of menstruation. She had had normal menses from the age of 1 up to 5 months before admission. She then missed 2 periods, which was followed by a scanty period and there had been none since. At the same time hair appeared on her upper lip, chin, cheeks, chest and buttocks. Hair grew long upon her arms and legs and became darker. Her voice deepened. She had no pain or any other symptoms. Her figure resembled a young male adult with male hair distribution. There was hypertrophy of the clitoris and slight hypertrophy of the labia. The pelvic organs were normal except for loss of uterine ovarian sensitivity. There was no hypertension. The blood counts and the chemistry were normal. Basal metabolic rate, visual field, and glucose tolerance tests were normal. X-ray films of skull, chest, and abdomen showed no abnormality. Air insufflation roentgenograms showed an ovoid tumor of the outer portion of the left adrenal. The right adrenal appeared normal. The excretion of male hormone in her urine was approximately 90 international units in 24 hours. During the same period she excreted 33 rat units of female sex hormones. At operation an ovoid tumor of the outer portion of the left adrenal was resected from the inner or normal portion through a left oblique transperitoneal approach. She made an uneventful recovery. Her menses returned to normal months after operation.

the excretion of excess androgens in the urine disappeared and there was a gradual diminution of the male characteristics and a restoration of the repressed female appearance and function

Changes in a male child toward adult masculinity The usual syndrome described with adrenal cortical tumor in a male child has been that of precocious puberty (pubertas praecox). In a very few cases tumors of the pineal gland have been responsible for sexual precocity in boys (Weinberger and Grant). Three cases have been reported as having been caused by tumors of the testis (Sacchi, Moreau, Parkes-Weber, and Rowland). A number of cases have been described in the literature without any proved cause. Among these has been a description of its familial tendency without tumor by Rush, Bilderback, Slocum, and Rogers under the term macrogenitosomia. The occurrence of the syndrome as caused by adrenal cortical tumor is uncommon. Kepler summarized its frequency as 12 times among 37 known adrenal tumors in children, a proportion of about 2 female children with pseudo-pubertas praecox to 1 male with pubertas praecox.

Fig 10 Case 7 Air insufflation x-ray films showing both adrenals. The ovoid mass above the left kidney clearly shows as an adrenal tumor.

Among the earlier cases was that reported by Linser in 1903, a boy of 5 with a left adrenal tumor with metastases. The second was by Adams in 1905. Player and Lissner re-

Fig 8

Fig 8 Case 7 RR, 18 years, with a tumor of the left cortical adrenal with androgenic changes for 6 months. Her figure is male, her breasts flat. She has hirsuties.

Fig 9

Fig 9 Case 7 RR, 1 year after removal of a left adrenal tumor. Her figure and breasts are feminine but some hirsutism has persisted.

Fig. 5 Air insufflation x-ray film of bilateral adrenal by periplasm in female 4 years of age with pseudosexual precocity. There was no tumor in this case.

She was again operated upon in April, 1941 and an ovoid tumor the size of a plum was resected off the lower pole of the right adrenal through lumbar incision. She made an uneventful recovery. Following the operation, she resumed her normal menstruation with the exception that they are accompanied by premenstrual pain, the first that she had had since the cessation of menses previous to the onset of the left adrenal syndrome.

Histological section of the right adrenal resembled that of the left. There were many cells containing lipid vacuoles.

These 2 cases presented tumors with secretion of marked excess of androgens. The androgens in both produced masculinization, less in the case with less hormones and marked in the case of excessive excretion. The diagnosis was confirmed in each by air insufflation x-ray films.

Removal of the tumors in each of these was not accompanied by acute adrenal deficiency because with only excess androgens secreted there was no reasonable expectation of function atrophy of the opposite adrenal. The uneventful recoveries support that reasoning. Following the removal of the tumors

Fig. 6.

ported that up to 1932 only 8 authentic cases were found in the literature and they added theirs as the 9th. They also called attention to

2 cases reported in the literature by Laborde and by Marquand both of which had not been proved.

Cases of the syndromes must occur rarely without reporting either because of the marked advance of the disease before recognition, so that no operative procedure was undertaken and no autopsy was possible to prove the diagnosis. Broster in an exhaustive study of the subject recorded only 1 case of a male child with prematurity. Ian Fraser has recently published the occurrence of precocious puberty in a child of 1 year. From the few cases recorded the occurrence of pubertas praecox with adrenal tumor in male children is among the rarer adrenal tumors.

We have studied 5 male children with prematurity 5, 6, 8, 11 and 11 years of age. The 3 youngest presented masculine hair on genitalia, body beginning on the face associated with enlargement of the penis. In these 3 the testes were not proportionately enlarged. The 3 children were much larger than normal for their age and showed advance dentition and epiphyseal development. They had no adiposity or other metabolic change. Two showed no change in sella, no evidence of pituitary enlargement, no change in the thymus and nor

Fig. Case 7 Air insufflation ray film of her normal the time her left adrenal tumor as operated upon

Fig. 3 Case 7 Air insufflation ray film year later showing the beginning of rounded tumor growth of the lower part of the right adrenal

mal sized adrenals by air insufflation x-ray films One case, aged 6 years, showed a normal adrenal on the right and a large adrenal on the left by air insufflation x-ray film This was not confirmed because no operation was permitted and the case was removed from study after operation was suggested

Two boys, aged 11 years, showed marked hirsutism and hypertrophy of the genitals, including the testes Their symptoms had been present, one for 8 and the other for 7 years Their advancing maturity showed itself by fusion of all the epiphyses with apparent shortening of the extremities, and with their continued facial and muscular growth they resembled achondrodystrophic dwarfs but x-ray studies definitely disproved this dystrophy Both had prostatic secretion and sperm One of these boys showed no apparent change from normal in his adrenals by air insufflation x-ray films The other had an increase in size of his right adrenal No determination of its pathology was possible as no operative procedure was permitted These cases resembled closely the description of familial pubertas praecox reported by Rush et al

CASE 8 An additional case was observed by one of us (case of Dr O Pickhard) in a boy of 5 years in

Fig 15 Case 7 Drawing showing the rounded tumor of the lower end of the right adrenal as disclosed at operation

the terminal stage of the syndrome This patient showed facial and neck obesity, as well as body obesity, genital hypertrophy, and a huge abdominal tumor

Fig 14 Case 7 Air insufflation x ray film 1½ years after operation, showing the increase in size of the rounded lower end of the right adrenal as compared with Figure 13

Fig 16 Air insufflation x ray film of a boy of 6 years with prematurity The right adrenal was normal, the left enlarged, whether hyperplasia or tumor not ascertained

Fig. 7 Case 9. Air insufflation ray film in male of 53 with some feminizing symptoms. The left adrenal is definitely enlarged and looks like tumor on its inner side. \ operation permitted

Operative results on the few boys with the syndrome have had a very high mortality. In addition to the prematurity most obviously due to the effect of androgens, there appears very frequently symptoms suggestive of the changes seen with Cushing's syndrome and probably resulting functional atrophy of the opposing adrenal. In Fordyce and Evans case practically no adrenal tissue was found at autopsy on the opposite side. Playter and Lissner's case the first surgical recovery in this group showed only the androgenic effect in his masculine maturity and in the acceleration of his epiphyseal growth. He showed no evidence of acute adrenal deficiency following the removal of his tumor and made an uneventful recovery.

TUMORS WITH EXCESS ESTROGENS

Only 6 definite cases of tumors with excess estrogens producing changes in the adult male toward femininity have been reported. The first was by Bittorf in 1919 a male of 26 years noticed decrease in the size of his testes and enlargement of his breasts. He became impotent and developed a tumor in the left side of his abdomen. Cachexia and death followed and autopsy (Matthias) showed a "malignant adrenal cortical hypernephroma." Zum Busch re-

ported a similar case with secretion from his breasts and the cause verified by autopsy. Holl reported a patient 15 years old who was operated upon the diagnosis established, but the tumor impossible to remove. He reported a second patient, 44 years old, with similar symptoms in which the tumor was removed by operation and recovery. Following recovery there was a subsidence of breasts, adiposity and varicoceles and a return of libido and sex function. Lissner published autopsy findings in a male of 33 years with breast enlargement and secretion and an adrenal cortical carcinoma. Simpson and Joll in 1938 published an exhaustive investigation into a patient, aged 34 years, who had feminization due to an adrenal carcinoma and excreted an excess of estrogenic hormone (probably estrone). The excess of hormone disappeared after the operation and returned with the recurrence of the tumor in the form of metastases. From the report of their case it is apparent that considerable proof is offered to explain the symptomatology of theirs and the previous cases.

Among the various cases referred to the Squier Clinic for adrenal determination was the following

CASE 9. H.F. Chart \ 496369, Presbyterian Hospital, aged 53 years, as admitted in 1937 with a gnawing sensation in his stomach. He noticed that for 3 years before admission his hair had become finer than previously and was increasing over his body. He gained weight and his breasts began to increase and be noticeable. He noticed rather marked decrease in his penis and testes and a complete loss of desire and libido. He became easily fatigued and nervous. Areas of pigmentation developed upon his hands face and neck. His blood pressure low. He had a slight erythrocytosis, a normal sugar tolerance and normal blood chemistry. X ray studies of his head and chest showed no particular abnormality. Perirenal air insufflation x ray films showed large right adrenal and marked increase in the size of his left. Hormonal studies were not made due to his departure. There was no determined cause for his feminization but from observation upon hundreds of air insufflation studies of the adrenals he presented a shadow which showed a left adrenal many times the size of that normally seen and from its anatomical change suggested adrenal pathology.

From the few cases in the literature and especially from the one reported by Simpson and Joll, the adrenal in these cases was directly

responsible for the feminization, and the adrenal tumor cells were the source of the estrogenic hormone producing the symptoms. It was also shown by Simpson and Joll that androgens were still excreted by their patient. They attempted to show that histologically their case differed from an adrenal cortical tumor producing androgens, in one case of such with which they were familiar. Both tumors had numerous vacuolated cells, probably lipoids. They were unable to find fuchsin staining granules in the cells of the estrogenic tumor but they were present in the cells of the virilizing tumor. In the estrogenic tumor the cytoplasm of the cells were reported as diffusely fuchsinophilic. They suggested that from some studies on normal adrenals it appeared that granules were present in males in the inner layer of the cortex. In females they were not present except in patients over 50 years of age. Sudds in investigations on much larger number of adrenals, finding that granules are present in both sexes, concluded that they had little to do with sex and considerable to do with age.

Two of the reported patients with estrogenic tumors recovered from the operation when the tumor was removed and in neither was removal of the tumor followed by acute adrenal deficiency.

TUMORS WITH SYMPTOMS DUE TO EXCESS ANDROGENS AND OTHER HORMONES

From a study of the literature tumors with symptoms due to excess androgens and other hormones are not as infrequent as the others. In the large number of cases referred to us for determination of the adrenal status, this type appeared in many of the cases. A large number of the patients showed no apparent anatomical change in either adrenal. A considerable number had hypertrophy of one or both adrenals. A few had tumors as a causation. From the literature it probably is the most frequent type of tumor seen.

The syndrome was described by Cushing and he first suggested that it occurred with basophilic adenoma of the pituitary. The symptoms and clinical picture of his syndrome are characteristic of these types of adrenocortical tumors. Cushing outlined a clinical

Fig. 18. Case 10. Air-insufflation x-ray film in a woman of 36 years with a small right adrenal cortical tumor and a tiny left adrenal. Her symptoms were androgenic as well as of the Cushing's type.

picture consisting of a rapid, plethoric, painful obesity, affecting primarily the face, neck, and abdomen but usually sparing the limbs, thus giving rise to an obesity described as the "buffalo type." The facial changes made the eyes appear small and slit-like, resembling a pig's eye. There was acrocyanosis, with purplish linear atrophiae on the lower abdomen and the thighs. Hirsuties was marked. There was a tendency toward polycythemia and hypertension and glycosuria was of frequent occurrence, as were high blood cholesterol readings. With the syndrome was muscular weakness and porosis of the bones causing a cervico-dorsal stoop and a shortening of the stature. Amenorrhea was present in the females and impotence in the males. There was a marked susceptibility to infectious processes and to physical stress. Mental changes were present, and in some, well developed psychoses occurred.

Since the description by Cushing, many reports have been issued as to the findings in these cases in which opinions have varied as to the causation. Some believe it mostly pituitary (Pardee). Others reported that it was more frequently associated with adrenal changes (Oppenheimer et al., Silver, etc.). Some similar syndromes have been reported

Fig. 9. Case. Air insufflation ray film in case of 40 years old boye tumor of the right adrenal cortex. The air did not diffuse between the liver and the tumor because those fascial planes were sealed by adhesions.

as having been associated with thymic tumors. A few rare cases with obesity and hypertension as well as hirsuties have occurred with the arrhenoblastomas described by Robert Meyer.

From a study of the recorded cases with the probable causation factors as far as hormonal changes have been registered upon the patient some of the changes could most likely have been due to the effects of excess androgens. These changes were the hirsuties, amenorrhea and changes in the secondary sex organs as breasts and clitoris. Some of the cases exhibited these changes to a marked degree others less. The fat deposits, the skin the poly cythemia, the hypertension, and glycosuria as well as the weakness and osteoporosis can best be explained by excess hormones present, disorganizing such metabolic processes. Bauer called attention to the fact that these in their main effects were the opposite to Addison's disease and that most of these individuals were suffering from an excess of metabolism steroids produced by the adrenal either by itself or through stimulation of the pituitary. Considerable support to this has been offered by clinical observers and by investigators.

When tumor occurs the cases may vary from those with marked sex changes and milder Cushing type changes to those with less marked sex changes and mostly of the syndrome described by Cushing.

The following 3 cases show the variations.

CASE 1. L.P. Chart No. 450260, Presbyterian Hospital, reported 936 married woman aged 36 years was admitted 1935 with loss of hair of her scalp excess of hair over her body and absence of menstruation for 3 years. She had become stouter and was very nervous and had attacks of palpitation. There was hypertrophy of her clitoris. She had mild erythrocytosis but her chemistry, basal metabolic rate, etc. were normal. X-ray films of skull, chest and abdomen showed no abnormality. Cystoscopy and pyelography were normal. At laparotomy X-ray films showed an ovoid tumor of the right adrenal and small left adrenal. She excreted 66 international units of male hormones in 24 hours. During her stay here as slightly and depressed at times and emotionally unstable. Her right adrenal tumor was removed through oblique transperitoneal incision. She developed an acute adrenal deficiency, and in spite of saline, blood, and the then available cortical extracts she died following convulsion 3 hours after operation. Autopsy permitted.

The tumor on section was very cellular and not well encapsulated, and through most of the tumor were cells in sheets cords, and nests. The cells are large with pale vesicular nuclei and indistinct nuclei. There was an occasional mitosis and tumor cells were found in the adjacent to the tumor. There were areas of necrosis. The cytoplasm of the cell was abundant granular and many were so vacuolated as to be foamy.

CASE 2. L.F., Chart No. 249269, Presbyterian Hospital, reported 1936, female, aged 36 years, was admitted 1939 with headaches, palpitation, excessive growth of hair and cessation of menses for 3 1/2 years. She was married and had two children. Her face and hands were reddened, dark, and puffy and she had edema of shoulders and abdomen and stricture of abdomen and thighs. There was marked emaciation and heat. There was an indistinct mass in the right flank, hypertrophy of the clitoris and insensitivity of the ovaries. She showed an erythrocytosis normal blood chemistry high basal metabolic rate low sugar tolerance, and hypertension. She excreted 8 rat units follicular hormones in her urine in 24 hours. X-ray studies of skull and chest showed no abnormalities. The right kidney was low but no abnormality by pyelogram. Air insufflation X-ray film showed large mass between the right kidney. The air did not diffuse between the liver and the mass. This mass an adrenal tumor was removed through transperitoneal approach. It was adherent to liver and vena cava. She developed an acute adrenal deficiency 24 hours but

Fig 20

Fig 20 Case 12 Air insufflation x ray film in a woman of 40 years with androgenic symptoms as well as Cushing's, showing a similar irregular mass above the right kidney resembling Case 11

Fig 21

Fig 21 Photograph of Case 12, showing duskiness of hands and neck, cervicodorsal stoop, trunk and face obesity, and thinness of hands and legs, abdominal striae, and mild hirsuties

recovered with saline and blood transfusions. Her menses returned after 2 months and her hair diminished in amount. She returned to her marital status with return of libido. Six months later she developed headaches and her menses became scanty at first and then ceased. X-ray films showed lung metastases. The hair growth, duskiness of hands and feet, and edemas progressed. When she died no autopsy was permitted.

The tumor on section showed that the morphology was almost identical in all parts. There was no resemblance to a normal adrenal. There were many mitoses and cellular invasion of the stroma. Many cells were vacuolated and foamy cells were frequent.

CASE 12 E. G., Chart No. 304917, Presbyterian Hospital, a female, aged 40 years, was admitted in 1939 with complaints of hair on body, increased fat deposits, and absence of menses. For several years her entire appearance had changed with gain of fat on face, neck, chest, and abdomen with loss of size of arms and legs. Her face, chest, and hands were reddened. She had marked striae on the abdomen and thighs. With this change her menses had ceased. She had dyspnea and edema of her feet. Her clitoris and labia were enlarged. She had erythrocytosis, a normal blood chemistry, a low basal metabolic rate, and low sugar tolerance and a high

blood cholesterol reading. There was moderate hypertension and a rather moderate cervical dorsal stoop. X-ray films of her skull, bones, and chest showed no abnormalities. Air insufflation of the perirenal space showed an apparent large mass above a low right kidney resembling that in Case 11. There was no follicular hormone in her urine and only a small amount of follicle stimulating hormone was present. Male hormonal excretion determination was not done. She was not operated upon but condition became worse and she returned to Poland. Since then she has been untraced.

These 3 cases appear to be illustrative of the variations produced by different effects. The first had well marked effects of excess androgens and moderate other metabolic disturbances and the last with slight change in sexual characteristics and well marked metabolic disturbances. These cases differed markedly from the 2 younger women in the emotional balance. In fact it seems as if the Cushing type tumor appears more frequently in the older group of women. The cases with only androgen syndromes were stolid, not nervous.

Fig. 2.

Fig. 2. Case 3. Photograph of female aged 27 years with syndrome of Cushing's type without androgenic changes. She had a tumor of her left adrenal cortex.

Fig. 3.

Fig. 3. Case 3. Air infiltration x-ray films in which the air diffusing poorly shows a normal sized right adrenal and tumor of the left adrenal above her left kidney.

took all examinations without any disturbance. Those with the other changes were nervous, apprehensive, and difficult to handle. The demonstration of the tumor by air injection became less clearly defined as the patients developed fatty deposits and edemas. In 1 case the second the air did not diffuse between the tumor and the liver or around the mesial aspect. Operation disclosed that tumor adhesion had sealed the fascial planes in this area. The last patient, not operated upon, presented a similar air infiltration x ray film. The first case was proved to have an excess of male sex hormones excreted in her urine. The second case most probably had a large excess but at that period there was no satisfactory process available for its estimation. She however excreted normal amounts of female hormones. The 3 patients operated upon developed postoperative symptoms of acute adrenal deficiency. One patient died in spite of therapy now known as inadequate. The other patient recovered from her acute deficiency. We thought at first the recovery was brought about by our therapeutic endeavors but later

experience leads us to think that the hormonal production of her unrecognized metastases may have played the major part in her recovery.

TUMORS WITH CHANGES DUE TO EXCESS OTHER STEROIDS RELATED TO METABOLISM

CASE 3. L.G. Chart N. 500497 Presbyterian Hospital, a female aged 27 years, was admitted 937th marked depression melancholia. At the suspected endocrine pathology 1 1/2 years before admission she was a normal married woman working as a journalist and editor. She then underwent marked change: personality, lost interest in her surroundings, contact and body needs. At the same time her menses ceased and fine silky growth of hair appeared upon her face body and extremities. There was no resemblance of male distribution. There was swelling and dusky color of face and hands. Ring of neck, shoulders and abdomen with trace on her abdomen. She had cervical thoracic stoop. She was apathetic and sat long periods without speaking or moving and walked falteringly. She stated that she was mentally unbalanced. Her clitoris was small as were her pelvic organs. She had a erythrocytosis, normal blood hemistry with high cholesterol reads 400 mg. A low sugar tolerance and a normal basal metabolic rate. There was mod-

erate hypertension. The x-ray films revealed no abnormalities of head, chest, or bones. Perirenal air insufflation x-ray films were difficult to read because of poor diffusion of the air. However, by serial readings a normal appearing right adrenal was identified and a triangular shaped tumor on the left was noted. There were no demonstrable male or female sex hormones in her urine by our ordinary comparative examinations. At operation a left adrenal tumor was removed through a subcostal transperitoneal incision. She reacted excellently from the anesthesia and on recovery from unconsciousness was talkative, and chatty, greeted her relatives the first time since the onset of her syndrome and stated that she no longer felt unbalanced. Her relatives declared she acted like her former self. She was given large amounts of saline and commercial cortical extract then available. In 20 hours she developed acute adrenal deficiency, was benefited slightly by transfusion and cortical extract but died after a convulsion in 23 hours after the operation.

A complete autopsy showed Cushing's syndrome (clinical) hirsutism (silly, not masculine) adiposity, adenoma of adrenal cortex, left, (surgically removed), atrophy of adrenal cortex, right, encephalomalacia, frontal, right, fatty liver, normal ovaries, thyroid and pineal. In the pituitary, all basophiles showed marked hyaline changes in their cytoplasm. Partial to complete disappearance of the granules, vacuolization and disfiguration of the nuclei (Crooke syndrome).

The left adrenal tumor showed a small group of cells alternating with much larger cells which had a foam cell appearance. The true adrenal cortical zones were not seen. The group of cells seen were large, polygonal, possessing oval nuclei with distinct nucleoli and were at times vacuolated. The foam cells appeared multinuclear with rather small nuclei and pale framework within the cytoplasm. A tendency to giant formation was rarely seen.

This patient had the symptoms described as Cushing's syndrome with cessation of menstruation, the only real change of sexual character. No male or female urinary hormones were identified by the usual examination. The complete autopsy did not reveal any change in the pituitary except that described by Crooke. It is to be deduced that the adrenal cortical tumor produced the changes manifested by her symptoms for the 2 years prior to her operation. The death was due to acute adrenal cortical deficiency. The remaining adrenal was apparently atrophic and inactive. In retrospect the tumor must have produced sterols in abundance as was evidenced by the histological sections in which most of the cells were foamy with lipoids. These sterols were

Fig. 24. Case 13. A drawing of the tumor and kidney at the time of operation.

neither of androgenic nor estrogenic influence as was shown by her symptoms and the failure to identify either in her urine. From her symptoms and acute death following the removal of the tumor they apparently had to do with the life maintenance properties of the adrenal.

DIAGNOSIS WITH AIR INSUFFLATION X-RAY FILMS

For the purpose of ascertaining the anatomical change in the adrenal gland we have used the x-ray studies of air insufflation into the perirenal fascial spaces. We have previously reported upon this technique, as have Roome, Mencher, and others. Normal adrenals are usually well visualized if sufficient air is introduced in the proper plane. The right adrenal more frequently shows as a long thin wedge between the liver and the psoas and the left as a less dense wider wedge or crescent above the left kidney. When tumor is present it is more clearly shown in thin people. The tumors are round when small, ovoid when larger, and may be lobulated when very large.

Fig. 2

Fig. 2. Case 3. Photograph of female aged 27 years with syndrome of Cushing's type without androgenic changes. She had tumor of her left adrenal cortex.

Fig. 3

Fig. 3. Case 3. Air insufflation x-ray film in which the air diffusing poorly shows normal sized right adrenal and tumor of the left adrenal above her left kidney.

took all examinations without any disturbance. Those with the other changes were nervous, apprehensive, and difficult to handle. The demonstration of the tumor by air infiltration became less clearly defined as the patients developed fatty deposits and edemas. In 1 case the second, the air did not diffuse between the tumor and the liver or around the mesial aspect. Operation disclosed that tumor adhesion had sealed the fascial planes in this area. The last patient, not operated upon, presented a similar air infiltration x-ray film. The first case was proved to have an excess of male sex hormones excreted in her urine. The second case most probably had a large excess but at that period there was no satisfactory process available for its estimation. She however excreted normal amounts of female hormones. The 2 patients operated upon developed postoperative symptoms of acute adrenal deficiency. One patient died in spite of therapy now known as inadequate. The other patient recovered from her acute deficiency. We thought at first the recovery was brought about by our therapeutic endeavors but later

experience leads us to think that the hormonal production of her unrecognized metastases may have played the major part in her recovery.

TUMORS WITH CHANGES DUE TO EXCESS OTHER STEROIDS RELATED TO METABOLISM

CASE 3. L.G. Chart N. 509497 Presbyterian Hospital, female aged 27 years was admitted 1037 11th marked depression, melancholia and 11th suspected endocrine pathology. Up to 3 yrs. before admission she was normal married mother, working as journalist and editor. She then underwent marked change in personality lost all interest in her surroundings contacts, and body needs. At the same time her menses ceased and fine silky growth of hair appeared upon her face and extremities. There was no resemblance of male distribution. There was swelling and duskliness of face and hands, swelling of neck, shoulders, and abdomen with tissue on her abdomen. She had cervical thoracic goop. She was apathetic and sat long periods without speaking or moving and walked falteringly. She stated that she was mentally unbalanced. Her clitoris was small as were her pelvic organs. She had erythrocytosis a normal blood chemistry with high cholesterol reading. A low sugar tolerance and normal basal metabolic rate. There was mod-

Estrogens Frank early called attention to the excretion of large amounts of estrogens in the urine of patients with the adrenogenital syndrome and with virilism. In our former article we called attention to the large or normal amounts so excreted. Slot and Kepler each reported cases in which there was no excess. In the series of Levy, Simpson, de Fremery, and MacBeth, a slight excess of estrogenic hormone occasionally occurred. In our present reported cases we have shown that in young girls with virilism due to a tumor a high amount of estrogens was excreted before the tumor was removed and continued unchanged after removal of the tumor and the virilism had recessed.

Of particular necessity is the estimation of the estrogens in those rare cases of males with femininity due to adrenal cortical tumor. Here, Simpson and Joll have shown that excess estrogens were evidently present before the tumor was removed, disappeared after the tumor was removed, and recurred with reappearance of the tumor. The estrogen excreted was considered to be estrone.

The identification of other kosteroids associated with adrenal cortical tumors is as yet in an unknown state. An increase in substance which maintains life was demonstrated in the blood stream of a patient with hyperfunction of the adrenal cortex (Cushing's syndrome). The identification of like-maintaining substances in the urine in normal persons and their increase under stress has been reported by Weil and Browne. There are as yet no reports upon cases of adrenal syndromes in which these other types of steroids have been identified in the urine, or whether their amount can vary according to the adrenal symptoms.

OPERATIVE PROCEDURES

Three different routes of approach have been used for removal of the adrenals (1) extraperitoneally, through the lumbar region, (2) transthoracic route, and (3) transperitoneal route.

The lumbar route with extraperitoneal approach has been used extensively in adrenal operations by Crile. It has been used for removal of tumors by many operators. Wal-

Fig. 26. Section removed in Case 5, a female without hormonal symptoms. The tumor was of an aberrant adrenal. Sheets of cells of somewhat uniform size arranged in places resembling the different zones of the adrenal. Lipoid vacuoles are rare. The adrenal tumor from the other female without hormonal symptoms had similar histology. $\times 160$.

ters, with as extensive experience as any, has used this route and has done bilateral exposures to determine first the diseased side and second to observe whether there was an opposing adrenal. Young devised an ingenious retractor fashioned after the rib-spreader retractor for chest operative procedures, and used the retractor for simultaneous bilateral exposure. The lumbar route has been used by us in adrenal operations upon the nontumor cases. It was used in 3 tumor cases: (1) a small pleochromocytoma of the adrenal, (2) a small tumor of the lower pole (Case 7), and (3) one of the larger nonhormonal tumors occurring in a male. This latter was difficult to deliver, was attached to the anterior capsule of the kidney, and the tumor ruptured through the capsule when attempts were made to visualize the tumor vessels before clamping and ligature. It was necessary to remove the kidney with the tumor.

The transthoracic approach was used by Broster in cases of nontumor adrenogenital syndromes. This, he claimed, was the easiest approach in view of the fact that the adrenal vessels allowed a slight range of upward movement. It has, however, the disadvantage of creating an artificial pneumothorax. It also was necessary to do a preliminary laparotomy for exploration of the adrenals by palpation, and then after recovery to perform the main operation by the transthoracic approach.

Fig. 5. Section removed in Case 3, male without hormonal symptoms. The cells in places are gigantic with large amounts of cytoplasm and huge nuclei. Lipoid vacuoles are rare. All male cases without hormonal symptoms had similar histology. $\times 60$.

All of the tumors so diagnosed by us were confirmed by operation. In a number of cases in which no tumor was shown on the air insufflation x ray films, but with some hypertrophy apparently present, operative procedures have always demonstrated that the adrenal was exactly as outlined. It was especially valuable when tumor was present and small and unrecognizable by any other method, except operation. It will also show the presence of the opposite adrenal if one is the seat of a tumor. In children and in thin adults the air diffusion is easy and gives clear shadows. In obese and especially in those with Cushing's syndrome the air diffuses poorly because of the fatty edema in the perirenal tissues. In these patients a series of films may outline parts of the tumor so that a composite film may be made. For the purpose of demonstrating adrenal anatomy in our hands the use of air insufflation has been without complications and without fatalities. If used often it can lead to an increase in the fibrous tissue in the perirenal fat and by some this has been considered to be a hindrance during operation. Compared with the diagnostic aid obtained by its use in our hands, the increased fibrosis of the perirenal fascia was of no consequence.

The autographic x ray film by the method of Reynaldo dos Santos has been used by some but the dangers of thorotrast have been since shown to make this media hazardous.

HORMONES

Androgens. The earlier work of the estimation of the androgenic hormones was by the capon comb growth. The method is better standardized but difficult and expensive. The colorimetric method when used, as by Callow with proper caution as to procedure and interpretation, is simpler and less expensive and time may prove its value. There is definite agreement that virilism and adrenal cortical tumors are associated with high levels of androgen excretion and this high androgen excretion declines to lower levels after operation.

The determination of the particular hormone or hormones producing androgenic effect is a difficult procedure requiring high output values in the urine and large amounts for assay. The hormone of the adrenal that has been isolated in this manner has been shown to be dehydroisoandrosterone a beta kosteroid and is different from the hormone of the testis testosterone an alpha kosteroid. Under certain conditions the beta kosteroids are greatly increased in quantity, as in patients with hyperplasia, adenoma, and carcinoma of the adrenal cortex, and may be of value in diagnosing Cushing's syndrome due to pituitary basophilism from that due to adrenal cortical change.

In the excretion of androgens there appears to be a rather definite relation to the amount of male virilism and with the amount of androgens in the urine. The more marked the symptoms the higher the assay.

Another kosteroid with androgenic action has been isolated from the urine, particularly that by Butler and Marrian (pregnane). This apparently was associated only with that adrenal tumor. The identification of this particular kosteroid required large amounts of urine and with mechanics and talent not available in many laboratories. Its identification was not useful for purposes of preoperative diagnosis.

There is a need of a simple and fairly reliable estimation of all the androgens excreted so that the results may be quickly available to be applied in a survey of the symptoms of each case. It is needed because the symptoms of androgenic excess are more frequent than any other.

Estrogens Frank early called attention to the excretion of large amounts of estrogens in the urine of patients with the adrenogenital syndrome and with virilism. In our former article we called attention to the large or normal amounts so excreted. Slot and Kepler each reported cases in which there was no excess. In the series of Levy, Simpson, de Fremery, and MacBeth, a slight excess of estrogenic hormone occasionally occurred. In our present reported cases we have shown that in young girls with virilism due to a tumor a high amount of estrogens was excreted before the tumor was removed and continued unchanged after removal of the tumor and the virilism had recessed.

Of particular necessity is the estimation of the estrogens in those rare cases of males with femininity due to adrenal cortical tumor. Here, Simpson and Joll have shown that excess estrogens were evidently present before the tumor was removed, disappeared after the tumor was removed, and recurred with reappearance of the tumor. The estrogen excreted was considered to be estrone.

The identification of other kesteroids associated with adrenal cortical tumors is as yet in an unknown state. An increase in substance which maintains life was demonstrated in the blood stream of a patient with hyperfunction of the adrenal cortex (Cushing's syndrome). The identification of like-maintaining substances in the urine in normal persons and their increase under stress has been reported by Weil and Browne. There are as yet no reports upon cases of adrenal syndromes in which these other types of steroids have been identified in the urine, or whether their amount can vary according to the adrenal symptoms.

OPERATIVE PROCEDURES

Three different routes of approach have been used for removal of the adrenals: (1) extraperitoneally, through the lumbar region, (2) transthoracic route, and (3) transperitoneal route.

The lumbar route with extraperitoneal approach has been used extensively in adrenal operations by Crile. It has been used for removal of tumors by many operators. Wal-

Fig. 26. Section removed in Case 5, a female without hormonal symptoms. The tumor was of an aberrant adrenal. Sheets of cells of somewhat uniform size arranged in places resembling the different zones of the adrenal. Lipoid vacuoles are rare. The adrenal tumor from the other female without hormonal symptoms had similar histology. $\times 160$.

ters, with as extensive experience as any, has used this route and has done bilateral exposures to determine first the diseased side and second to observe whether there was an opposing adrenal. Young devised an ingenious retractor fashioned after the rib-spreader retractor for chest operative procedures, and used the retractor for simultaneous bilateral exposure. The lumbar route has been used by us in adrenal operations upon the nontumor cases. It was used in 3 tumor cases: (1) a small pleochromocytoma of the adrenal, (2) a small tumor of the lower pole (Case 7), and (3) one of the larger nonhormonal tumors occurring in a male. This latter was difficult to deliver, was attached to the anterior capsule of the kidney, and the tumor ruptured through the capsule when attempts were made to visualize the tumor vessels before clamping and ligation. It was necessary to remove the kidney with the tumor.

The transthoracic approach was used by Broster in cases of nontumor adrenogenital syndromes. This, he claimed, was the easiest approach in view of the fact that the adrenal vessels allowed a slight range of upward movement. It has, however, the disadvantage of creating an artificial pneumothorax. It also was necessary to do a preliminary laparotomy for exploration of the adrenals by palpation, and then after recovery to perform the main operation by the transthoracic approach.

Fig. 27. Section of tumor removed in Case 6, female with only marked androgenic symptoms. The cells stain deeply, are large in places but not like the nonhormonal male. The cytoplasm contains abundant granules and also many lipid vacuoles and some foam cells. $\times 60$.

We have felt that with both the lumbar and transthoracic route, the operator is too handicapped by the inadequacy of the incision and the impossibility of ligation of the vessels before the tumor is manipulated. It also is impossible to be familiar with the location of the other viscera and vessels from within the limited area above the renal pole. We think that either will give an adequate exposure for small normal or slightly enlarged adrenals. We have had no experience in the bilateral incisions of Young in adults or in cases with tumor. It is satisfactory in children with small hypertrophy of the adrenals and may be with tumor.

The transperitoneal approach that we recommended in our former report has been to us most satisfactory for an adequate exposure and to offer the greatest freedom in proper handling of a tumor especially if it is large. The direction of growth of a tumor of the adrenal is downwards and anterior both in the direction of the incision. The location of other viscera and of the vessels is easier and the reparation of the posterior peritoneum is possible quickly and well. There have been no weaknesses in the abdominal wall subsequent to the operation.

POSTOPERATIVE ACUTE ADRENAL DEFICIENCY

Many cases have been reported with what has been described as shock occurring immediately or shortly following the removal of

an adrenal tumor. Cecil stated that 39 per cent died of this shock and that 66 per cent had severe shock from which 27 per cent of all patients operated upon recovered. The other 33 per cent apparently had no shock.

It is now accepted by most clinicians and investigators that the characteristic collapse is that of acute adrenal cortical deficiency. We have seen this collapse in the removal of a renal carcinoma which invading the adrenal necessitated the adrenal's removal with the perinephritic fat and the tumorous kidney. The collapse terminated fatally and autopsy disclosed that the only metastases from the renal tumor were in the opposite adrenal which had been destroyed. From a perusal of the literature and from our own experience it does not occur in the nonhormonal adrenal cortical tumor cases, or in the pure sex hormonal type cases but occurs in those which show the effects of excess hormonal action upon many metabolic factors: the electrolytes, the water and salt balance, the capillary permeability. In fact the symptoms seen in the Cushing's type whether in children or in adults. It has been advanced on reasonable grounds that in these cases the changes can only be produced by excess hormones. It has been shown experimentally that excess life maintenance substance can cause atrophy of the adrenals. Clinically in those cases ending fatally it has been shown that contra-adrenal atrophy is present with the Cushing type tumors. It has been our experience to have a

Fig. 28. Section of tumor removed in Case 7, female with only androgenic symptoms. The cells are fairly uniform, stain deeply, have numerous fine granules, and many lipid vacuoles and some foam cells. $\times 60$.

patient of this type recover from the adrenal collapse without administration of a potent adrenal extract but later recognition of secreting metastases elsewhere offered the explanation. Broad and Broad reported such a case in which they first attributed the recovery to frequent administrations of adrenaline.

Walters and Kepler stated that the most important factor in surgical therapy of adrenal cortical tumors is the anticipation, prevention, and control of postoperative cortical deficiency. In this we concur but call attention to the mechanism as mostly only occurring in those of Cushing's syndrome, because with the androgenic type tumor there is no functional atrophy of the opposing adrenal.

The method is that used in the crisis of Addison's disease, having on hand and administering preoperatively and postoperatively potent adrenal hormone. A potent extract of the cortex may be used as furnished by Kendall to Walters and Kepler, or desocycorticosterone in adequate doses may be used. In addition to the hormone there is administered by oral or parenteral administration adequate amounts of sodium chloride and sodium citrate. Since the marked cases of Cushing's syndrome have an erythrocytemia, but apparently a marked diminished blood volume, an immediate postoperative transfusion is necessary. It is considered possible that a diet low in potassium might be of value for some time preceding the operation.

Fig 29 Section of tumor removed in Case 11, a woman with androgenic and Cushing's symptoms. The cells are uniformly of carcinoma, some granules in the cytoplasm, and many lipid vacuoles and foam cells are present $\times 160$

Fig 30 Section of tumor removed in Case 13, a woman with only Cushing's symptoms and no androgenic changes. The entire tumor was composed of huge cells filled with lipid vacuoles, like foam cells. Only in a few places were cells containing granular cytoplasm as is shown in this field $\times 160$

In 1937 Ingle and Kendall reported that they were able to prevent the atrophy of the adrenals experimentally when large doses of active adrenal cortical substances were given, by the use of an anterior pituitary extract which had high adrenotrophic activity. To date there has been no report as to its effects given preoperatively upon the Cushing syndrome cases, to produce reactivity of the opposing functionless adrenal cells.

Walters and Kepler believe that they have been able to tide the patient over the crisis by replacement therapy and that the remaining adrenal tissue will regain its capacity to produce a sufficient amount of hormones to meet the needs of the body. Since the potent steroid has been available we have not had a marked Cushing's syndrome type tumor, and from our experience, those cases with androgenic changes do not need replacement therapy if an opposing adrenal can be demonstrated by air insufflation x-ray film.

PATHOLOGY

The tumors were either adenoma or carcinoma. The adenomas were soft, encapsulated tumors and histologically did not show any invasive characteristics. The cells were typical of the adrenal cortex of no particular zone and showed lipid vacuoles which compared roughly in number with the degree of hormonal changes.

The carcinomas varied. In the 2 nonhormonal tumors in male adults the cells were frequently of giant size with giant nuclei. They resembled various parts of the adrenal. Lipoid vacuoles were rare. Sections of the specimens obtained from the females without hormonal syndromes again resembled each other. They differed from similar males in the relative rarity of the giant cells and nuclei and the variability of their appearance. At times sheets of cells resembled the glomerular zone; other places the fasciculate; and again the reticulate. In other places they were undifferentiated. They resembled sections of renal hypernephromas. In the cells lipoid vacuoles were infrequent.

Sections of the carcinomas associated with hormonal changes varied. One showed invasion of the capsule and cells in the blood vessels. The cells were in sheets resembling some parts of the adrenal cortex, more frequently the glomerular and reticulate layer. Numerous vacuoles were present. The other had cells mostly undifferentiated with many mitoses and numerous vacuoles present. The number of cell vacuoles again roughly appeared to vary with the amount of hormonal changes.

The more the syndrome approached the Cushing type the more marked was the amount of vacuoles which were present. In the last case with only the syndrome of the Cushing type present, the number of vacuoles present was so great that most of the tumor was composed of foam cells.

In review of our attempts to correlate the finding of fuchsinophilic granules with the symptoms of the disease has still left us unable to decide whether their presence has or has not any particular association with the various types of cases.

Fuchsinophilic staining of the cytoplasm was present in all the tumors, in some diffusely and in others in granules. It apparently was more pronounced in cases with hormonal syndromes.

SUMMARY

1. Adrenal cortical tumors may occur with or without hormonal syndromes or with hormonal syndromes.

2. The hormonal syndromes may be due to an excess of androgens or estrogens or other as yet unidentified hormones.

3. The syndromes are determined by the type and amount of hormone or hormones produced and by the sex and age of the patient.

4. The status of the adrenals may be adequately shown by air insufflation x ray films.

5. Removal of adrenal tumors by the transperitoneal route is surgically best.

6. Acute adrenal deficiency occurs only or mostly in those with symptoms described as Cushing's syndrome.

7. The therapy of this is similar to that which is used in the acute deficiency crisis in Addison's disease.

8. Histologically the tumors that produce the hormonal syndromes have cytoplasmic lipoid vacuoles in amounts comparable to the symptoms.

the development of anatomic lesions escapes detection and cannot be identified by the senses

Though one does not deny that purely functional phenomena are the predominant pathogenic factors, it is doubtful that they are the only ones, and it becomes less doubtful when one observes cases of evident permanent obstruction to the flow of bile which has lasted for several years and has been controlled only by means of an operation for drainage of bile

Nowadays, in accordance with the modern trend of surgery based on clinical observations at each and every operation one can state by physiological standards that in the presence of any abnormal condition the living body has an anatomic substratum which exists only during life but which either disappears when death takes place or is transformed by death

Hypertrophy of the sphincter of Oddi The occurrence of hypertrophy of the sphincter of Oddi after cholecystectomy has been established beyond doubt by experimental research (Rost). Therefore, it is logical to assume that the same thing occurs in man. It is also logical to believe that hypertrophy is one of the factors producing a resistant papilla. The same phenomenon is frequently found in the cardia and in the rectum, in which the obstructive agent is the sphincter with its marked hypertrophy

It is important to understand that a permanent, real anatomic factor is always added to spasm. The increased amount of contractile tissues about the sphincter, which conflicts with the anatomic and functional conditions of the common bile duct under control of the sphincter, favors the production of stagnation. Similar physiopathological facts are necessarily present in some cases, even in noncholecystectomized patients, because lithiasis in itself creates conditions similar to those which follow cholecystectomy. Moreover, lithiasis is equivalent to cholecystectomy in man. The local edema, hyperemia of the tissues and local congestion, in addition to hypertrophy of the sphincter, will complete the transient sphincteral obstruction or else they will prevent complete closure of the

sphincter in the intervals of muscular relaxation. Infection may be a helpful, although not an indispensable, factor

It is possible that in the 8 cases reported by Strauss the pathogenic mechanism corresponded to the aforementioned physiopathological facts. Strauss' patients complained of pain crises simulating hepatocolic pain without jaundice. At operation it was found that the gall bladder was inflamed but without stones, pericholecystitis was present and the hepatic and common bile ducts were dilated. Cholecystectomy was performed, but shortly afterward the patients suffered attacks similar to those which they had had before operation. A second operation was performed. It was found difficult to insert even a fine catheter through the lumen of the ampulla of Vater which was of increased consistency and the seat of infiltration. The patients were subjected to dilatation of the lumen of the ampulla of Vater, 4 were operated on a third time for recurrence of attacks. This time, choledochoduodenostomy was successful. In some of the patients the ampulla of Vater was the size of a nipple, was red, inflamed, and congested

Anatomic obstruction The more attention one gives to the anatomic obstruction of the sphincter of Oddi the more significant are the clinical observations. A series of cases presenting permanent obstruction at the sphincter of Oddi have been reported during the last few years, by Haberer, Sturm, Melchior, Floercken, and Colp and Doubilet (6). The existence of the anatomic substratum of stenosis of the papilla of Vater in the presence of gall-bladder disease either with or without calculi or concretions is frequent, whereas it is rarely observed at necropsy—a factor which depends on the many changes which take place during life. Physiological conditions may change at any time, a stricture of the duodenal papilla may disappear with the consequent restoration of normal tonus in the sphincter of Oddi as well as the re-establishment of the normal morphology of the biliary tree

Physiological investigations are being carried on with due consideration of the fact that the elimination of bile through the hepatic and

FUNCTIONAL DISTURBANCES OF THE CHOLEDOCHUS AND HEPATIC BILE DUCTS

PABLO I. MIRIZZI, M.D., F.A.C.S. (Hon.), Córdoba, Argentina

IN 1917 surgeons believed that spasm or increased tonicity of the sphincter of Oddi, was the factor which by mechanical action caused biliary pain and jaundice. Shortly afterward, results of experimental research were reported which showed that cholecystectomy is frequently followed by incontinence of the sphincter of Oddi which in turn is followed by muscular hypertrophy of the sphincter as reported by Rost. In 1925 Del Valle reported his observations on obvious structure of the papilla of Vater seen during operation performed on cholecystectomized patients suffering from pain crises.

Further reports of experiments, as well as of findings during operations and of postoperative observations directed the attention of surgeons to the sphincter of Oddi. In 1929 Westphal, Gleichmann and Mann (34) were able to establish that, from a functional point of view, the antral upper part of the sphincter of Oddi is vagotonic whereas the lower part is sympathotonic, as shown by faradic irritation in association with pharmacodynamic substances.

About the same time that functional disturbances in animals were reported I observed by means of operative cholangiography, spasms of the sphincter of Oddi in patients whose biliary tract had been operated upon.

In 1930, Nauw, Muscel and Pavel reported cases of jaundice due to reflex spasm of the sphincter of Oddi which was classified as functional jaundice. Other cases were reported by Pavel and Jonckheere. More recently several surgeons and research workers, including Walters and Doubilet and Colp (10) observed by means of manometry in addition

to postoperative cholangiography, the presence of spasm after the administration of certain substances.

In 1940 I presented before the National Academy of Medicine of Buenos Aires a series of clinical observations and roentgenograms made during the operation which indicated that the existence of abnormal spasm of the hepatic duct was capable of producing biliary stagnation (21).

Method used. I studied the functions of the biliary tree by means of operative cholangiography. The procedure (19) consisted in the majority of cases in injecting through the cystic duct from 3 to 5 cubic centimeters of iodized poppyseed oil at the rate of 1 cubic centimeter a minute. A slow injection is important in order to prevent a sudden distention of the biliary tree. By this method the operation is performed under the best physiological conditions; the registered phenomena can be correctly interpreted and, at the same time, the pathological conditions can be clearly differentiated from the normal. Up to the present, this study includes 800 cases of biliary lithiasis which have been systematically observed by means of operative cholangiography.

THE SPHINCTER OF ODDI

The majority of surgeons believe that a more or less prolonged spasm of the sphincter of Oddi is the only cause of biliary stagnation. They believe that the free flow of bile is obstructed by the increased tonicity of the sphincter, the intensity and rhythm of which are controlled by several factors, in particular by diseases of the gall bladder and concretions.

The Chinese aphorism "the sum of the parts is not the total" can be applied to the field of medicine. The functional factor which according to Bergmann is the *primum moriens* in

Chief of the Surgical Clinic, Faculty of Medicine of the University of Córdoba.

Presented before the Clinical Congress of the American College of Surgeons, Boston, November 2-— 34.

Niessen, 27), "dyssynergia of the common bile duct" (Best and Hicken), "biliary dyskinesia" (Ivy), "papillitis," "sphincteritis" (Walters), "resistance of Vater's papilla," "scleroretractile choledoch-odditis" (Del Valle)

Classification Any extreme classification will be either insufficient or exaggerated. I believe that the term "odditis" for all the phenomena of obstruction will properly cover the field. Odditis is then divided into dystonia and stenotic odditis.

Dystonia is evidently exhibited as a functional disorder—there is incomplete closure of the sphincter due to spasm in the distal sympatheticotrophic part of the sphincter only. This functional disturbance causes a reflux toward the duct of Wirsung. The phenomenon must occur in a larger number of cases than is shown by operative cholangiography. The two ducts do not open into the ampulla of Vater in all cases, and also it may not be possible to detect the phenomenon in the operative cholangiogram (see Fig. 3). Dystonia may be compared with the type of dysthyroidism of the dualists, whereas early stenotic odditis may be compared to hyperthyroidism. The former is due to a dissociated function, whereas the latter is due to an increased one. Therefore, the name dystonia is proper for that functional disorder.

Stenotic odditis is a term applied to any type of resistance of the ampulla of Vater without specifying the causes of the more or less permanent obstruction at the sphincteral segment. In some cases the resistance is due to true total hypertonicity of the sphincter of Oddi. Sclerotic retraction occurs only in rare cases.

Now then, operative cholangiography deals with the problems of the various types of dystonia and stenotic odditis with an essentially physiological criterion. Moreover it fulfills all the requirements necessary to reduce the causes of error to a minimum. The injection of the opaque substance is made slowly and in very small amounts, thus distention of the bile ducts and the entrance of foreign matter in the hepatobiliary system are prevented and the anatomic integrity of the ducts

is well preserved. The main objection to the use of large doses of opaque substance is that such doses provoke phenomena of spasm and thus facilitate the immediate entrance of the injection material into Wirsung's duct. This occurrence may lead the surgeon to believe that there are biliary disturbances present. The latter can also be erroneously suspected from the enormous dilatation of the biliary tree which was caused by the injection but which can be wrongly interpreted as being caused by stagnation. Examination of the bile ducts through a fistula or with a T-shaped tube should be even more severely criticized. Choledochotomy, the presence of a tube in the lumen of a delicate duct, the increased pressure, and the large dose of opaque substance in the bile ducts are factors which necessarily disturb the physiology of the ducts and modify their morphology.

Dystonia In accordance with the hypothetical statement previously made concerning the normal physiology of the hepatobiliary system, the common bile duct evacuates its contents through the papilla of Vater while in relaxation. Any factor which partially disturbs the contractile mechanism of the papilla produces dystonia, which may be compared with experimental hypotonic stagnation (Westphal) provoked by the contraction of the sympatheticotrophic portion of the sphincter of Oddi. Quick entrance of the opaque substance (lipiodol) into the duct of Wirsung during operative cholangiography is a clear indication of dystonia. It is possible that in a certain number of cases transient spasms of a dissociated character are not noticeable during the operation because of the lack of reflux into the pancreatic duct, due to the absence of the ampulla of Vater. Cases of this type, under the circumstances, are therefore included in the group of stenosing odditis. In our series 4 per cent of cases were classified as dystonia.

Some investigators (Desplas, Moulounguet, and Malgras) believe that the entrance of an opaque substance into the duct of Wirsung has no pathological significance. They are led to this conclusion because of their method of carrying out the operation: the injection into the gall bladder or into the common bile duct

¹Although the term "odditis" appears throughout this article the Editors of SURGERY GYNECOLOGY & OBSTETRICS neither accept nor endorse it as good usage.

common bile ducts is the explanation of the harmoniously co-ordinated functions in which peristalsis of the common bile duct, contraction of the hepatic duct, and the tonus of the sphincter of Oddi are equally important. From pathogenic and physiological angles, a papilla of Vater of normal patency in the presence of hypertrophy of the common bile duct constitutes a more or less evident obstacle to the papilla. Dilatation of the biliary tract indicates a functional disturbance even in the absence of any anatomic lesion. A spastic hypertonic papilla in a choledochus with normal tonus is also an obstacle against which the duct reacts with detrimental effect to its energy and muscular ability, thus producing dilatation of its lumen and elongation and sinuosity of the duct.

The study of transverse sections of the distal choledochal segment including the sphincter of Oddi revealed in 50 per cent of the cases of lithiasis evident muscular hyperplasia, especially annular hyperplasia, and a moderate hyperplasia of the longitudinal and oblique muscular fibers.

Muscular hyperplasia was so great in these cases that after further evolution, it caused the limiting zone between the muscular rings of the sphincter to disappear. Increase of the connective tissue was also observed in some cases, especially in those in which muscular hyperplasia did not occur. Increase of both the muscular and connective tissues occurred in some cases (Westphal 33). These anatomic changes may take place in the choledochal segments of the sphincter of Oddi, even though the common bile duct does not contain stones.

Choledochitis and anatomic obstruction of the papilla of Vater. In 1908 surgeons of the French school, especially Gossset, discussed before the Congress of Surgery in Paris the rôle of stenotic and nonstenotic inflammation of the common bile duct without stones in the production of biliary stagnation and in the development of jaundice. Later Charrier and Thalheimer, also surgeons of the French school, reported their observations in 27 cases of choledochitis without concretions and described the lesions which were observed in the common bile duct, the hepatic duct, the gall

bladder and the pancreas. A group of cases of choledochitis which is secondary to cholecystitis and biliary stagnation and which follows the evolution of these conditions, is clearly differentiable in the 27 cases. The appearance of the common bile duct in some cases of this group resembles a pipe (the so called *tuyau de pipe* of French surgeons). The lumen of the duct becomes narrower with each recurrence of the inflammation until finally it is so small that even a fine probe cannot pass through. In such cases, the phenomena of biliary stagnation are aggravated by the spasm of the sphincter of Oddi. Choledochitis is an added factor of irritation (Brocq). Cases of either partial or diffuse inflammation of the common bile duct constitute a group of surgical cases of choledochitis in which interstitial sclerosis involves not only the walls of the duct but those of the ampulla of Vater as well (Chabrol and Klotz).

Argentinean surgeons, especially Del Valle, called attention to a group of cholecystectomized patients who had been operated on for the so called choledochal syndrome, namely hepatocolic pain. Oddi's sphincter was stenotic (retractile choledochoddyitis). The process of inflammation was verified by microscopic studies. I have in my files the record of a case of choledochitis with stricture of the papilla of Vater. A brief résumé of the record follows.

Series 1. Case 24. A woman, aged 43 years, suffered from repeated attacks of hepatic pain and jaundice which were over as quickly as they appeared. A enlarged gall bladder (the size of duck egg), 5 centimeters in length without tones and with thick walls, was surgically removed. The cystic duct was in free communication with the common bile duct, which was like rigid tube the size of the little finger. Its walls were 3 millimeters thick. A stricture of the ampulla of Vater and the absence of calculi were disclosed by means of operative cholangiography. Papillary fibrous stricture was found during duodenostomy. The ampulla of Vater was incised. The patient recovered.

Nomenclature. The names applied to the alterations in the sphincter segment of the common bile duct vary widely because of the lack of consistency in the understanding of their etiology and pathogenesis. They include spastic cholepathy (Schmieden and

Niessen, 27), "dysynergia of the common bile duct" (Best and Hicken), "biliary dyskinesia" (Ivy), "papillitis," "sphincteritis" (Walters), "resistance of Vater's papilla," "scleroretractile choledoch-odditis" (Del Valle)

Classification Any extreme classification will be either insufficient or exaggerated. I believe that the term "odditis"¹ for all the phenomena of obstruction will properly cover the field. Odditis is then divided into dystonia and stenotic odditis.

Dystonia is evidently exhibited as a functional disorder—there is incomplete closure of the sphincter due to spasm in the distal sympathetic part of the sphincter only. This functional disturbance causes a reflux toward the duct of Wirsung. The phenomenon must occur in a larger number of cases than is shown by operative cholangiography. The two ducts do not open into the ampulla of Vater in all cases, and also it may not be possible to detect the phenomenon in the operative cholangiogram (see Fig. 3). Dystonia may be compared with the type of dysthyroidism of the dualists, whereas early stenotic odditis may be compared to hyperthyroidism. The former is due to a dissociated function, whereas the latter is due to an increased one. Therefore, the name dystonia is proper for that functional disorder.

Stenotic odditis is a term applied to any type of resistance of the ampulla of Vater without specifying the causes of the more or less permanent obstruction at the sphincteral segment. In some cases the resistance is due to true total hypertonicity of the sphincter of Oddi. Sclerotic retraction occurs only in rare cases.

Now then, operative cholangiography deals with the problems of the various types of dystonia and stenotic odditis with an essentially physiological criterion. Moreover it fulfills all the requirements necessary to reduce the causes of error to a minimum. The injection of the opaque substance is made slowly and in very small amounts, thus distention of the bile ducts and the entrance of foreign matter in the hepatobiliary system are prevented and the anatomic integrity of the ducts

is well preserved. The main objection to the use of large doses of opaque substance is that such doses provoke phenomena of spasm and thus facilitate the immediate entrance of the injection material into Wirsung's duct. This occurrence may lead the surgeon to believe that there are biliary disturbances present. The latter can also be erroneously suspected from the enormous dilatation of the biliary tree which was caused by the injection but which can be wrongly interpreted as being caused by stagnation. Examination of the bile ducts through a fistula or with a T-shaped tube should be even more severely criticized. Choledochotomy, the presence of a tube in the lumen of a delicate duct, the increased pressure, and the large dose of opaque substance in the bile ducts are factors which necessarily disturb the physiology of the ducts and modify their morphology.

Dystonia In accordance with the hypothetical statement previously made concerning the normal physiology of the hepatobiliary system, the common bile duct evacuates its contents through the papilla of Vater while in relaxation. Any factor which partially disturbs the contractile mechanism of the papilla produces dystonia, which may be compared with experimental hypotonic stagnation (Westphal) provoked by the contraction of the sympathetic portion of the sphincter of Oddi. Quick entrance of the opaque substance (Ipiodol) into the duct of Wirsung during operative cholangiography is a clear indication of dystonia. It is possible that in a certain number of cases transient spasms of a dissociated character are not noticeable during the operation because of the lack of reflux into the pancreatic duct, due to the absence of the ampulla of Vater. Cases of this type, under the circumstances, are therefore included in the group of stenosing odditis. In our series 4 per cent of cases were classified as dystonia.

Some investigators (Desplas, Moulouguet, and Malgras) believe that the entrance of an opaque substance into the duct of Wirsung has no pathological significance. They are led to this conclusion because of their method of carrying out the operation: the injection into the gall bladder or into the common bile duct

¹Although the term "odditis" appears throughout this article the Editors of SURGERY, GYNECOLOGY & OBSTETRICS neither accept nor endorse it as good usage.

of a large dose of the opaque substance with increased pressure sometimes through a fistula or by means of a drain tube.

The circumstances under which operative cholangiography is performed vary, and one may conclude that the flow of the opaque material into the duct of Wirsung when not caused or provoked by a defective method of injection is far from being a mechanical and passive phenomenon. One is convinced that the flow into Wirsung's duct is an active phenomenon which is caused by the current of the biliary tree flowing into the pancreatic tree. This would seem to indicate that at certain times the current flows in an opposite direction, namely from Wirsung's duct to the biliary tree. Several factors indicate that the entrance into Wirsung's duct is an abnormal active phenomenon of pathological significance which might explain the disturbed function (dystonia). Some of these factors are

1. The unmistakable evidence during observation of the two different phases, namely in the first phase total closure of the ampulla of Vater and in the second phase partial opening of the ampulla with persistence of the sympathicotrophic ring of Oddi's sphincter by which the flow of the opaque substance into Wirsung's duct is permitted (Figs. 1 and 2).

2. The fact that in certain cases the opaque substance may be seen in the first film occupying only the terminal segment of Wirsung's duct and, shortly after the substance may be observed filling the entire duct (Figs. 3 and 4).

3. The contour of the duct is modified by pre-existing stagnation. The duct looks sinuous, moniliform and increased in diameter. The fusiform dilatation of the segment of the duct near the ampulla of Vater indicates that the excretory functions of the duct are pathological. The ampulliform aspect of the terminal segment of the duct is the most evident proof of stagnation which little by little modifies the architecture of the duct at the part where it opens into the ampulla of Vater (Figs. 2 and 5).

4. The associated lesions and the further progress of the disease, as observed in a group

of patients with dystonia, seemed to indicate intimate relations between the two excretory systems. Cholecystitis dissecans, also called exfoliative cholecystitis, was present in 1 case. In another case the presence of a calculus and reflux into Wirsung's duct were observed during operative cholangiography (Fig. 5). In this case Kehr drainage was applied and the fistula healed well. Later however the common bile duct ruptured with consequent choleperitoneum. In other patients not properly treated for stagnation the crises of pain recurred repeatedly as a result of functional disturbances and the patients had to submit to other operations.

ROENTGEN ASPECTS

Dystonia. The retention of injected material in the pancreatic duct is transient. Within a few minutes, when the sphincter is in complete relaxation the duct empties its contents at the same time that the contents of the biliary tree are evacuated. The duct of Wirsung in the cholangiograms appears sinuous, dilated and moniliform, that is, it has a morphological aspect which indicates repeated increased tension on the duct, both because of the stagnation of the pancreatic secretion and because of the reflux of bile. In cases of dystonia, the biliary tree is somewhat dilated and sometimes elongated and sinuous as a result of biliary stagnation. In some cases, it may be observed that the biliary and the pancreatic trees form at times one united system as they meet at the level of the ampulla of Vater.

Inflammatory stenosis of the sphincter of Oddi. Stenosing odditis varies in intensity from simple hypertonicty to complete obstruction of the sphincter of Oddi. The former is comparable to experimental hypertonic choledochal stagnation (Westphal) the latter depends on anatomic factors such as retractile sclerosis (Del Valle). My personal statistics give an average frequency of 1 per cent.

Stenosing odditis is identified by the stagnation of the opaque substance into the biliary tree 15 or 20 minutes after having been injected into the tree.

The contour of the ampulla of Vater is the most varied. It may be similar to the 'sharp

end of a pencil," "hookshaped," or in "the form of the tip of the finger" In most cases a small amount of opaque substance passes into the duodenum The whole biliary tree, down to the finest intrahepatic branches, appears in the different films throughout the operation The common bile duct is flexuose, elongated, and of an increased diameter It is almost always in active peristalsis, as shown by the undulations of its contour In some cases a general atony of the whole biliary tree may be observed

In the roentgenograms, the main structures for the excretion of bile present functional and morphologic aspects which indicate their constant strain against the resistance of the sphincter

RESULTS OF THE DISTURBANCES OF THE SPHINCTER OF ODDI

The functional sphincteral disturbances little by little cause anatomic lesions of the pancreas and of the biliary tree The cholangiograms in my own files show how frequently lipiodol enters the pancreatic duct, a result especially favored by dystonia I believe that biliary lithiasis, and particularly the functional disorders caused by the disease, predispose to the development of acute necrosis of the pancreas The fact that in a large majority of cases chronic pancreatitis is a sequela to biliary lithiasis supports my belief Dystonia may be revealed by operative cholangiography in 3 per cent of the cases In many of these cases the roentgenograms reveal the duct of Wirsung in its full extent Frequently its diameter is increased, a condition which proves that previous stagnation has been present By means of these operative observations, which prove beyond doubt the existence of functional disturbances in the main excretory route of the bile, it becomes easy to understand how such disturbances favor the entrance of bile into Wirsung's duct The disturbance in function is sufficient again and again to cause the establishment of communication between the common bile duct and the pancreatic duct These functional disturbances cannot be felt on palpation nor seen by the eye And yet, they become so marked that at times the diseased condition

of the gall bladder (cholecystitis) is disguised by the associated lesions of the biliary tract and pancreas

The reflux of bile into the pancreatic tree creates in itself an abnormal condition which is dangerous to the anatomic integrity of the pancreas The injection of from 30 to 60 cubic centimeters of serum into Wirsung's duct have been considered harmless because they do not cause macroscopic lesions (Estrade) There is no doubt, however, that they do cause anatomopathological lesions from internal trauma, tearing the fine pancreatic ducts and causing foci of glandular necrosis (Brocq)

The most complete statistical records of the past few years show that acute necrosis of the pancreas is a predominant complication of biliary lithiasis—a factor which proves the important relation between the two diseases (Schmieden, 28)

On the other hand, it cannot be denied that a calculus in any part of the common bile duct, especially in the ampulla of Vater, causes irritation which in turn favors spasm The stone provokes evident dystonia of the sphincter In several instances calculi have been found impacted in the ampulla of Vater during necropsy in the presence of pancreatic necrosis

In the Museum of Pathologic Anatomy I saw such an anatomic specimen (Ferraris), which had been taken from the body of an old man who died from pancreatic necrosis The calculus, the size of a grain of wheat, was impacted in the ampulla of Vater and the sharp end of it entered the lumen of the duodenum

It is also important to direct attention to the frequency with which acute pancreatic disorders are observed in vagotonic patients In 48 necropsies following death from pancreatic disease, biliary lithiasis was found in 28 instances In 10 of these the biliary tree did not show anatomic changes but the history showed justification for a presumptive diagnosis of neurosympathetic disorders (Stocker) All the aforementioned findings indicate the important rôle which the ampulla of Vater plays in the pathogenesis of diseases of the pancreas

Now then, the functional disturbances which follow reflux of pancreatic ferments evidently play an important part in the evolution of cholecystitis and in the pathogenesis of choledochitis. Certain factors observed in my patients indicate that in some cases pancreatic ferments play an important rôle in perforation of the gall bladder. The reflux of pancreatic juice into the bile ducts is a proved fact. However it becomes of pathological significance only when it occurs in the presence of sustained blockage of the bile ducts and in association with other factors which activate trypsin. Because of the blockage a large quantity of pancreatic juice enters into the gall bladder. The vesicular bile normally acid, becomes alkaline while at the same time the ferments are activated by the action of the infected bile (Colp, Doubilet and Gerber, 7).

On the other hand the fact is emphasized that the peculiar character of exfoliative and dissecant cholecystitis (23) depends on the action of the pancreatic ferments during their reflux into the common bile duct and the gall bladder. The reflux is favored both by dys-tonia of the sphincter of Oddi and by the great pressure of the juice in the pancreatic tree, which is higher than that of the bile in the biliary tree (Harms).

The general structure of the tunicae of the gall bladder which constitute the necrotic sac in these cases, can be identified by microscopic study because of the fact that the changes in the elastic and connective tissues are not marked notwithstanding the presence of great changes in the structure. This fact, which is of great pathogenic significance indicates that the lesions are caused by digestive ferments since the gangrene and suppuration which are caused by infection destroy the tissue structure to such an extent that it cannot be identified especially if there are vascular lesions which diminish the vitality and resistance of the tissues.

The reflux of pancreatic ferments most likely will play an important part in the production and development of choledochitis. It has been proved by experiments (Westphal) that besides choledochitis of the necrotic type followed by biliary peritonitis there can be

produced chronic, productive inflammation with destruction of the elastic tissues of the wall of the common bile duct and dilatation of the duct.

HEPATIC DUCT

Before a meeting of the Academy of Medicine of Buenos Aires, which was held October 22, 1937 with Professor B. Houmay as chairman, I presented my observations on the physiopathology of the extrahepatic bile ducts as seen by means of the operative cholangiography. I directed attention to certain phenomena which I had observed and which indicated that there really is a contractile mechanism namely a physiological sphincter at the level of the hepatic duct (20). Normal contraction of the sphincter separates the intrahepatic bile ducts from the extrahepatic branches of the biliary tree at times during normal elimination of bile. However in the course of diseases of either the intrahepatic or the extrahepatic branches of the biliary tree the contractile sphincter functions are disturbed to such a degree that one is justified in establishing the presence of a pathological process in the hepatic duct and its branches.

FUNCTIONAL SYNDROMES

A functional disturbance in the contraction of the sphincter of the hepatic duct prevents synergic action between the duct and other parts of the entire system of elimination of bile. From the knowledge gained by operative cholangiography it is evident that the disorder of sphincter contraction is an important factor in the production of pain and of biliary stagnation.

CASE 2. (No. 5 of series 6.) L. F. aged 31 years, was admitted to the hospital in October, 1937. She had had several attacks of typical biliary pain during the last few months before entering the hospital. She exhibited signs of myocarditis for which she had the proper treatment.

At operation chronic calculous cholecystitis was found. The patent cystic duct in the form of band crossed the main root of the biliary excretion at the front and opened into the internal border of the retroduodenal segment.

Operative cholangiography as performed. The first film after injection through the cystic duct showed the system of the hepatic duct to be rather dilated and injected. During operation the normal course of the cystic duct and the opening of the duct into segment lower than that in which the

Fig 1 Dystonia of the sphincter of Oddi. Total closure of the ampulla of Vater. The injection of 3 cubic centimeters of lipiodol was made through the cystic duct, *C12*. The system of the hepatic duct, *H*, contains lipiodol. The common bile duct, *C*, with dilated and undulated contours does not evacuate its contents into the duodenum because of total closure of the ampulla of Vater, *P*.

Fig 2 Roentgenogram of same patient as in Figure 1 taken 10 minutes later showing partial closure of the ampulla of Vater. The system of the hepatic duct, *H*, contains lipiodol. The common bile duct, *C*, has evacuated a portion of its content of lipiodol into the duodenum, *Dn*, through the ampulla of Vater, *P*. Lipiodol has flowed into the duct of Wirsung, *W*, the terminal segment of which is ampulliform.

Now then, the functional disturbances which follow reflux of pancreatic ferments evidently play an important part in the evolution of cholecystitis and in the pathogenesis of choledochitis. Certain factors observed in my patients indicate that in some cases pancreatic ferments play an important rôle in perforation of the gall bladder. The reflux of pancreatic juice into the bile ducts is a proved fact. However it becomes of pathological significance only when it occurs in the presence of sustained blockage of the bile ducts and in association with other factors which activate trypsin. Because of the blockage a large quantity of pancreatic juice enters into the gall bladder. The vesicular bile normally acid becomes alkaline while at the same time the ferments are activated by the action of the infected bile (Colp, Doubilet, and Gerber, 7).

On the other hand the fact is emphasized that the peculiar character of exfoliative and dissectant cholecystitis (23) depends on the action of the pancreatic ferments during their reflux into the common bile duct and the gall bladder. The reflux is favored both by dysfunction of the sphincter of Oddi and by the great pressure of the juice in the pancreatic tree which is higher than that of the bile in the biliary tree (Harms).

The general structure of the tunicae of the gall bladder which constitute the necrotic sac in these cases can be identified by microscopic study because of the fact that the changes in the elastic and connective tissues are not marked notwithstanding the presence of great changes in the structure. This fact, which is of great pathogenic significance indicates that the lesions are caused by digestive ferments, since the gangrene and suppuration which are caused by infection destroy the tissue structure to such an extent that it cannot be identified, especially if there are vascular lesions which diminish the vitality and resistance of the tissues.

The reflux of pancreatic ferments most likely will play an important part in the production and development of choledochitis. It has been proved by experiments (Westphal) that besides choledochitis of the necrotic type followed by biliary peritonitis there can be

produced chronic, productive inflammation with destruction of the elastic tissues of the wall of the common bile duct and dilatation of the duct.

HEPATIC DUCT

Before a meeting of the Academy of Medicine of Buenos Aires which was held October 22 1937 with Professor B. Housay as chairman I presented my observations on the physiopathology of the extrahepatic bile ducts as seen by means of the operative cholangiography. I directed attention to certain phenomena which I had observed and which indicated that there really is a contractile mechanism, namely a physiological sphincter at the level of the hepatic duct (20). Normal contraction of the sphincter separates the intrahepatic bile ducts from the extrahepatic branches of the biliary tree at times during normal elimination of bile. However in the course of diseases of either the intrahepatic or the extrahepatic branches of the biliary tree the contractile sphincter functions are disturbed to such a degree that one is justified in establishing the presence of a pathological process in the hepatic duct and its branches.

FUNCTIONAL SYNDROMES

A functional disturbance in the contraction of the sphincter of the hepatic duct prevents synergic action between the duct and other parts of the entire system of elimination of bile. From the knowledge gained by operative cholangiography it is evident that the disorder of sphincter contraction is an important factor in the production of pain and of biliary stagnation.

CASE (No. 5 of series 6). L. F. aged 37 years, was admitted to the hospital in October, 1937. She had had several attacks of typical biliary pain during the last few months before entering the hospital. She exhibited signs of myocarditis for which she had the proper treatment.

At operation chronic calculous cholecystitis was found. The patent cystic duct in the form of a band crossed the main route of the biliary excretion at the front and opened into the internal border of the retroduodenal segment.

Operative cholangiography was performed. The first film after injection through the cystic duct showed the system of the hepatic duct to be rather dilated and injected. During operation the abnormal course of the cystic duct and the opening of the duct at a segment lower than that in which the

The system of the hepatic duct, *H*, contains lipiodol. The common bile duct, *C*, with dilated and undulated contours does not evacuate its contents into the duodenum because of total closure of the ampulla of Vater, *P*.

Fig 2 Roentgenogram of same patient as in Figure 1 taken 10 minutes later showing partial closure of the ampulla of Vater. The system of the hepatic duct, *H*, contains lipiodol. The common bile duct, *C*, has evacuated a portion of its content of lipiodol into the duodenum, *Du*, through the ampulla of Vater *P*. Lipiodol has flowed into the duct of Wirsung, *W*, the terminal segment of which is ampulliform.

Fig. 3. Dystonia of the sphincter of Oddi. The injection of lipiodol, as made into the cystic duct. The common bile duct, C, contains lipiodol, Wirsung' duct, II, which is injected in its terminal segment, does not show because of its proximity to the image of the common bile duct. A little opaque substance has passed into the duodenum.

Fig. 4. Roentgenogram obtained minutes later than that in Figure 3. Lipiodol has flowed in greater quantity into the duct of Wirsung, II, which is visible in its entirety.

Fig 5 Dystonia and choledocholithiasis. The injection of lipiodol was made through the cystic duct. The intrahepatic biliary tree is dilated and filled with opaque substance. The terminal third of the common bile duct, C, contains a smooth stone. Cal, lipiodol has flowed into the duct of Wirsung, W, the terminal segment of which is visible, undulated, ampulliform. A small quantity of lipiodol has passed through the ampulla of Vater, P, to the duodenum.

duct normally opens were verified. The common bile duct, increased in diameter, was visible. A little lipiodol passed into the duodenum. The second film showed that the system of the hepatic duct was still injected. An accessory hepatic duct was identified. The diameter of the common bile duct was seen to have been reduced and the duct had evacuated almost all of its contents of opaque substance into the duodenum.

The first film indicates that retention of the opaque substance in the intrahepatic branches of the biliary tree depends on the transient action of an active obstructive factor at the level of the hepatic duct. The injection of the accessory duct could be explained by no other mechanism of action than this. The contraction of the upper part of the biliary tree was not sufficient at a given time to overcome the

resistance of the contracted hepatic duct. Moreover, it caused reflux of the opaque substance into the accessory hepatic duct which opened above the contracted segment of the hepatic duct. The phenomenon, in this case, is similar to that which occurs when the sympatheticotrophic part of the sphincter of Oddi is in contraction from dystonia and reflux into the duct of Wirsung takes place.

CASE 2 (No 7 of series 43) C M de P, aged 55 years, was an obese multiparous woman. Three years before she had suffered acute pain in the epigastric region, with nausea and vomiting spells. The attack was followed by jaundice and discoloration of feces for about 2 months. The crises of pain recurred at intervals.

Operation was performed May 30, 1940. The subhepatic space was blocked by strong adhesions.

Fig. 6. Functional syndrome of the hepatic duct. Roentgenogram taken 15 minutes after the injection. The hepatic duct system, *H*, is completely filled with the substance. Contraction of the distal segment of the hepatic duct (indicated by arrow) is the obstruction. The common bile duct, *C*, of almost normal diameter with repeated peristaltic movements makes lipiodol flow into the duodenum, *D*, through the ampulla of Vater, *P*. The opaque substance contained in the duct of Wirsung, *W*, is visible in the terminal third of the duct.

with the colon and the duodenum. The gall bladder had been reduced to fibrous sclema. The findings seemed to indicate that the structure had previously been in communication with the intestine through fistula which had healed. During dissection the cystic duct had been cut at the level of the common bile duct.

Operative cholangiography was carried out but because the cystic duct was missing it was necessary to inject the opaque substance directly into the common bile duct. The injection had to be made faster than usual because of the reflux of the substance over the lateral surfaces of the cannula.

The injection seemed to cause signs of dilatation or even anatomic disturbance of the common bile duct because of adhesions between the hilus of the liver and the neighboring structures. Therefore, 8 cubic centimeters of lipiodol was injected, or a dose almost three times that customarily used when the common bile duct is normal. The possible presence of a mechanical obstruction which as produced by calculi or some other cause as kept in mind because of the fact that jaundice had been present for so long time.

The rapid injection of the large doses caused distention of the biliary tree and spasms. The system of the hepatic duct appeared to be engorged with the

substance and the duct as strongly contracted. The diameter of the common bile duct was slightly increased and was peristaltic. The duct of Wirsung was filled with the substance. The ampulla of Vater had relaxed to allow passage of the opaque substance.

In the second film, obtained 15 minutes later the findings are the same (with slight variation namely the diameter of the common bile duct was reduced to normal, whereas the hepatic duct was distended above its distal segment which was in marked spasm (Fig. 6).

The results which follow the sudden distention of the biliary tree when the walls of the bile ducts are elastic and irritable are plainly shown by the aforementioned findings. These findings prove also that the circumscribed spasm of the distal segment of the hepatic duct causes more or less prolonged stagnation of the contents of the intrahepatic bile ducts. It is evident then that spasm of the hepatic duct causes slow progressive dilatation of the intrahepatic branches with consequent stagnation—the predominant patho-

genic factor of both transient jaundice and hepatic pain

Similar phenomena have been observed in several patients with subintrahepatic crises. The distention of the system of the hepatic duct, due to prolonged contraction of the duct which was verified in these patients, was the only explanation for the almost continuous hepatic pain. Neither the gall bladder nor the sphincter of Oddi played any part as causal agents. As seen by operative cholangiography, the gall bladder was in retractile sclerosis and deprived of all its functions of contractility. The cystic duct was obstructed, the sphincter of Oddi did not disclose any obstacle at the level of the ampulla of Vater. Now, by studying by means of operative cholangiography the association between the pathological anatomy and the clinical pathology and the function of the main route of elimination of bile, we have obtained sufficient data to support the statement that the hepatic duct system plays a most important part in the pathogenesis of hepatocolic pain.

SUMMARY AND CONCLUSIONS

1 The disturbances of the sphincter of Oddi are functional in a great majority of cases. The interference by a permanent, stenosing, anatomic factor are found to be rare.

2 Anatomic stricture of the ampulla of Vater is frequently associated with indurated thickening of the common bile duct (choledochitis).

3 The reflux of lipiodol into the duct of Wirsung is a characteristic roentgenographic finding in the presence of dystonia of the sphincter of Oddi. It represents a pathological phenomenon.

4 Functional disturbances in the sphincter of Oddi in association with reflux into the pancreatic duct are the cause of anatomic changes in both the pancreas and the biliary tract.

5 Functional disturbances in the hepatic duct may occur. In some cases the disturbances are the cause of the development of transient jaundice. The functional disorders of the hepatic duct in association with distention of its branches are quite frequently the

pathogenic factors which are involved in hepatic colic.

6 Roentgenograms and clinical proof of my theory stated herein were recently presented (22) in Buenos Aires, with the following conclusion: "In summarizing, *a posteriori*, without divorcing our belief from the general conception of the development, type, and course of biliary pain, it is evident that such a condition in which the factors of obstacle and infection play a rôle in varying proportions (Sprengel) is different in every patient. The degree of intensity varies with the individual because, as Leriche says, pain is like a lamp in an electric circuit, the glow and intensity of its light depending on the intensity of the electric current which passes through its circuit. Therefore there is no doubt that biliary pain, from a pathogenic point of view, is often a functional syndrome of the system of the hepatic duct only to which disturbances of the pancreatic tree, originating in dystonia of Oddi's sphincter, are sometimes added."

THE TREATMENT OF EXPERIMENTAL SHOCK BY THE INTRAVENOUS INJECTION OF DILUTE, NORMAL, AND CONCENTRATED PLASMA

EARLE B MAHONEY, M D, HARRY D KINGSLEY, M D, and
JOE W HOWLAND, Ph D, M D, Rochester, New York

THE treatment of traumatic shock demands the restoration of the depleted effective circulating blood volume. Large amounts of fluid and plasma protein are lost from the circulation, and these elements must both be replaced in the relative proportion that they have been lost. When dogs are shocked by intestinal trauma, the fluid which is lost from the peritoneal surfaces contains 3 to 4 per cent protein. This type of shock can be most efficiently treated by restoring to the circulation large amounts of half dilution plasma containing the same proportion of protein that has been lost. Treatment with more concentrated plasma solutions is less effective. The value of half dilution plasma in the clinical treatment of shock has been emphasized in a previous publication (10) and this finding conforms with the experimental results which are being reported elsewhere in the literature.

The widespread recognition of the value of plasma in the treatment of shock has been attested by the numerous publications discussing this subject during the past 2 years. The rapidly accumulating clinical experience, both in this country and in England, has established its efficacy in combating the shock resulting from hemorrhage, trauma, or burns. Plasma finds its greatest value in shock associated with a preponderant loss of the liquid elements in the blood, but it is also of unquestionable value in the emergency treatment of hemorrhage (3). Blood plasma may be preserved in the liquid form for a limited period, or in the lyophilic, or dry form, for an indefinite time. The various papers discussing the use of plas-

From the Departments of Surgery and Medicine of the University of Rochester School of Medicine and Dentistry and the Strong Memorial and Rochester Municipal Hospitals.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons Boston November 3-7 1941.

ma in shock have not been concerned primarily with the concentration to be injected. Alsever has used dilute plasma, but the most commonly used form has been whole plasma. Hill (8, 9) and his coworkers have advocated the use of 4 times concentrated plasma in both the prophylactic and therapeutic treatment of shock. This departure from the more common methods of treatment is strikingly convenient, but depends on the presence of available body water to restore the circulating blood volume.

The recognition that the diminished blood volume is one of the fundamental principles of shock has led to an exhaustive search for the method of its development and the location of the fluid lost. The theory of traumatic toxemia (Cannon) postulates a generalized capillary permeability resulting from a toxic product elaborated at the site of trauma. The importance of local fluid loss at the site of trauma was emphasized by Blalock and by Phemister, who produced shock by traumatizing the extremities of dogs. A tremendous amount has been written since that time, and it is clearly evident that many factors are concerned. These vary from the process involved after a simple hemorrhage from an artery to the complicated mechanism developing after a penetrating wound of the abdomen with minor bleeding. The rôle of the sympathetic nervous system (Freeman), the rôle of visceral capillary dilation (Moon) and that of potassium (Scudder) are all factors in the mechanism of fluid loss, but individually they do not appear to furnish adequate explanation. The increasing information regarding circulatory mechanics, water balance and electrolytes, endocrine dysfunction, and anoxia will eventually be correlated in a more concise understanding of the shock mechanisms.

TABLE I—THE BLOOD VALUES IN A CONTROL EXPERIMENT—DOG 40-333, WEIGHT 10.6 KILOGRAMS

	Hb vol	Ht vol C.	Hemoglobin per cent	Specific gravity	Plasma protein concentration per cent	Albumin concentration per cent	Globulin concentration per cent	Total solids—per cent

hr after trauma	390	1060	42	1.02				12
hr after trauma	397		40	1.023	15		9.5	20
hr after trauma	417	85	32.4	1.0234	12.15		9.6	

EXPERIMENTAL METHODS

Dogs weighing from 15 to 25 kilograms were used in all of the experiments and shock was produced by peritoneal trauma under nembutal anesthesia. A typical experiment was performed in the following manner. The dog did not receive food on the evening before, but was given water *ad lib*. On the morning of the experiment it was given .008 gram of morphine subcutaneously and half an hour later sufficient veterinary nembutal intravenously to produce narcosis. This method of administration was found to be the most satisfactory because of the great variation in the tolerance of the individual animal to nembutal. The control plasma volume was determined after one half hour of anesthesia, when the animal could be considered to have reached a basal level. The femoral artery was then cannulated and attached to a recording mercury manometer. The blood pressure tracing was recorded on a smoked drum. Blood sam-

ples were taken by jugular venipuncture with an 18 gauge needle without hemostasis except when the venous pressure was very low. The peritoneal cavity was exposed through a midline incision with careful hemostasis. The entire small bowel from the duodenum to the cecum was delivered and gently traumatized with a flat blade retractor. The bowel was held between the fingers and a uniform blow was delivered on the antimesenteric surface. It was necessary to repeat the trauma a second time when dealing with larger dogs. The fluid which exuded from the traumatized bowel was collected extraperitoneally and the bowel was covered with oiled silk to prevent evaporation. Plasma was injected intravenously by gravity and a Murphy drop bulb was inserted in the system to regulate the flow at 40 to 45 drops per minute.

Blood plasma was injected in three different concentrations, that is, as whole undiluted plasma, as one half dilution plasma, and as 4

TABLE II—A COMPARISON OF THE BLOOD VALUES WITHOUT ANESTHESIA, WITH NEMBUTAL ANESTHESIA ALONE, AND AFTER TRAUMA

Plasma volume	Blood volume	Hemoglobin	Total protein concentration	Total albumin concentration	Total globulin concentration	Total circulating protein	Total circulating albumin	Total circulating globulin	Remarks
								17	Control without anesthesia
	16					19		+	Control with anesthesia
26	36.8	—21	—	18	—46 (51 gm)	—67 (50 gm)	—45 (34 gm)	—22 (14 gm)	Shock—sublethal trauma
29	—29	—	29	29	—47 (26 gm)	—56 (36 gm)	—45 (18 gm)	—11 (8 gm)	Shock—sublethal trauma
29	—	+24	—	—	—48 (28 gm)	—53 (36 gm)	—45 (31 gm)	—12 (8 gm)	Shock—sublethal trauma
44	43	—14	21	—	—63 (36 gm)	—63 (36 gm)	—45 (30 gm)	—18 (20 gm)	Shock—sublethal trauma
47	2-43	+30	—	—	—64 (34 gm)	—64 (34 gm)	—45 (30 gm)	—19 (20 gm)	Shock—sublethal trauma
33	+			6	—66 (34 gm)	—67 (36 gm)	—45 (34 gm)	—20 (24 gm)	Shock—sublethal trauma

times concentrated plasma The half dilution was prepared by adding an equal volume of normal saline to whole plasma, and the 4 times concentrated by redissolving lyophile plasma in one-fourth the original volume of distilled water The prophylactic and therapeutic efficacy of these solutions was tested The prophylactic injection was started coincident with the trauma, the therapeutic injection was not started until the blood pressure had fallen below 80 millimeters of mercury

The volume of dilute and whole plasma injected corresponded to the dog's circulating plasma volume The prophylactic effect of 4 times concentrated plasma was tested with correspondingly large volumes The therapeutic effect was determined with the smaller amounts which have been suggested for clinical use

The peritoneal fluid was collected during the experiment and its protein content determined The animals were killed at the close of the experiment, and sections of the various organs were removed for microscopic study

Repeated observations were made of the arterial pressure, venous pressure, and circulation time Blood samples were collected in dry potassium oxalate (2 mgm /c c of blood) for determination of the hematocrit, plasma specific gravity, total protein concentration, albumin, and globulin The circulation time was determined by the sodium cyanide method (4) The protein concentration was determined by the micro-Kjeldahl method, and the albumin globulin ratio by Howe's method The gravimetric pipette was used in the determinations of specific gravity (4) The plasma volume was obtained by the direct blue dye method of Gibson and Evans, the spectrophotometer being used Correction for hemoglobin was made The accuracy of plasma volume determinations may well be questioned when the circulation is failing and the hematocrit is 50 per cent or more For this reason, only gross changes in volume have been considered significant

EXPERIMENTAL OBSERVATIONS

The typical reaction of a dog to trauma of the bowel is indicated in Graph 1 There is a primary fall in the arterial blood pressure

Graph 1 Control experiment Arterial and venous blood pressure in shock produced by intestinal trauma

during the first 2 or 3 hours of the experiment followed, in most cases, by a temporary secondary rise The blood pressure then gradually falls until the animal displays the typical signs of profound shock with peripheral circulatory failure

The time required after trauma for the blood pressure to fall and the survival time vary considerably in different animals The survival time averaged 8 hours, varying from 5 to 12 hours

The pulse rate is usually rapid and regular during the early hours of the experiment, but frequently decreases with the appearance of severe shock The venous pressure slowly declines and in profound shock it is impossible to withdraw blood from the veins

The blood findings in a typical control experiment are outlined in Table I The plasma volume slowly decreases throughout the experiment, with a parallel change in the total blood volume The change is less marked in the red cell volume calculated from the hematocrit, which indicates a retention of cellular elements in the presence of escaping fluid The red cell hematocrit becomes concentrated as the shock develops The specific gravity of the plasma decreases The concentration of the circulating total protein uniformly falls, and there is a marked decrease in the total circulating protein The circulation time increases as the arterial and venous pressures decline The fluid which exudes from the traumatized bowel is serosanguineous and has a protein content varying between 3 and 4 grams per 100 cubic centimeters

Dogs have been studied without anesthesia, with nembutal anesthesia alone, and with

Graph 2. Therapeutic effect of whole plasma. Dog 40-80.

anesthesia plus trauma. The blood and plasma volumes, the hematocrits, and the protein determinations are tabulated in Table II. The first two groups represent the average percentage changes in groups of experiments; the results in the shock group are tabulated individually. The most striking change noted in the shock group is the very marked fall in the circulating protein which varied from 32 to 66 per cent of the original content. These results correspond to the decrease in the plasma volume but are accentuated by the fall in the concentration of the circulating protein. The protein concentration has never increased in this type of shock. Nembutal anesthesia produces a dilution of the hematocrit in the normal dog due in part to stagnation of red cells in the spleen. The hemoconcentration

Graph 4. Therapeutic effect of dilute plasma. Dog 40-202.

Graph 3. Prophylactic effect of whole plasma. Dog 40-271.

present in shock is very striking because of the dilution in the control.

Shock treated with whole plasma. The injection of whole plasma in the shocked animal results in a temporary rise of the arterial and venous blood pressure. Dog 40-180 exemplifies the usual reaction to whole plasma (Graph 2). The injection of 250 cubic centimeters of plasma raised the blood pressure from 60 to 110 millimeters mercury. The effect was transitory and the animal died within $2\frac{1}{2}$ hours. The plasma volume was 965 cubic centimeters immediately following the injection and within 2 hours decreased to 500 cubic centimeters. The plasma injection caused a temporary dilution of the hematocrit and a temporary rise in the venous pressure. The prophylactic effect of whole plasma is indicated by the reaction of dog 40-271 (Graph 3). This dog received 800 cubic centimeters of plasma beginning at the time of trauma. In this type of experiment plasma does not prevent the initial fall in blood pressure but tends to stabilize it above

Graph 5. Prophylactic effect of dilute plasma. Dog 40-274.

TABLE III—THE EFFECT ON THE BLOOD VALUES OF HALF DILUTION PLASMA INJECTED THERAPEUTICALLY AND PROPHYLACTICALLY

	Plasma volume c.c.	Hematocrit	Total protein concentration	Total circulating protein gm	
Dog 40-202	805	53.9	6.86	55.0	Control
Therapeutic injection	570	69.8	5.10	29.0	Shock
	950	45.3	5.06	48.0	After plasma
Dog 40-274	570	59.6	5.45	31.1	Control
Prophylactic injection	600	52.7	5.03	34.7	4 hr after trauma
	645	65.7	4.62	29.8	12 hr after trauma

the shock level. At the end of 12 hours the arterial pressure remained at 110 millimeters of mercury, and the venous pressure was within normal limits. The large amount of plasma maintained the plasma volume at a constant level throughout the experiment. The hematocrit did not change during the plasma injection, but gradually increased after the injection.

Shock treated with half dilution plasma Large amounts of dilute plasma will restore the circulation of the shocked dog to an approximately normal condition (Graph 4). Dog 40-202 received 700 cubic centimeters of dilute plasma, the plasma volume was increased to the normal level, and the hematocrit decreased. The blood pressure returned to the control level, and the venous pressure increased to within normal limits.

Injection of dilute plasma gives the most uniform response of all the concentrations tested. Dog 40-274 (Graph 5) was given 550 cubic centimeters of half dilution plasma starting immediately after trauma. The arterial and venous pressures, as well as the plasma volume, were maintained at the nor-

mal level for 16 hours. The dog's general condition seemed excellent at the end of this time, but the experiment was terminated by sacrificing the animal. The results in 5 experiments have been similar to that of dog 40-274. Table III illustrates the effect of dilute plasma on the plasma volume, hematocrit, and total circulating protein.

Four times concentrated plasma The effect of injecting a relatively large quantity of the concentrated plasma is illustrated in Graph 6. Dog 40-341 received 200 cubic centimeters with no appreciable effect on the arterial pressure. The venous pressure was fairly well maintained until death. The plasma volume decreased from 774 to 400 cubic centimeters 1 hour before death. In this type of experiment the plasma specific gravity and the plasma protein concentration increase as would be anticipated. The therapeutic effect of the concentrated plasma is apparently variable as an occasional dog did survive longer than dog 40-341. In an occasional experiment of this type, the plasma volume would remain essentially unchanged during the injection, but

Graph 6 Prophylactic effect of concentrated plasma Dog 40-341

Graph 7 Therapeutic effect of concentrated plasma Dog 41-15

Graph 8 Therapeutic injection of concentrated plasma, 45 cubic centimeters of saline given by stomach tube. Dog 4 6.

In spite of this the blood pressure fell followed by the death of the animal

Four times concentrated plasma has been injected intravenously into an animal with peripheral circulatory failure. If the amount used is comparable to the quantity which has been used in a patient suffering from shock, the effect on the blood pressure, venous pressure, and on the dog's general condition is negligible. Repeated experiments (6) have produced the same negative result, as demonstrated in Graph 7.

The use of four times concentrated plasma does not supply available water to replenish the depleted circulating plasma volume. Graph 8 represents an experiment in which the dog was given water by stomach tube when the blood pressure was 70 millimeters of mercury. The concentrated plasma was then injected intravenously but the circulation was not improved. It must be admitted that in this type of shock the absorptive surface of the bowel has been damaged by trauma, hence this may not be a fair trial of the oral administration of water supplemented by concentrated plasma.

The type of experiment in which concentrated plasma seemed to have a beneficial effect on the blood pressure is shown in Graph 9. The dog was given saline solution by subcutaneous injection when the blood pressure was falling. When the pressure had reached 70

Graph 9 Therapeutic injection of concentrated plasma, 40 cubic centimeters of saline injected subcutaneously. Dog 4 93.

concentrated plasma was injected. This was followed by a temporary improvement in the circulation.

ANALYSIS OF RESULTS

The type of peripheral circulatory failure produced by peritoneal trauma conforms essentially with that produced by the usual experimental methods. This is characterized by a fall in the arterial and venous pressures, a decrease in the plasma volume and a concentration of the hematocrit. The plasma protein concentration uniformly decreases. This is not in agreement with the more generally accepted concept of protein concentration, but does agree with the observations of Dunphy who found a decreased concentration in experimental burnshock. The most striking feature is the very marked decrease in the total circulating protein which raises the intriguing problem of determining its fate. A considerable amount can be recovered in the peritoneal exudate but at the present time it is not possible to state the proportion lost by this route. The data suggest that there is also a general loss of protein throughout the body but the experimental evidence is not conclusive. This will be discussed in a future publication.

The results indicate that dilute plasma is more efficient than concentrated plasma in the prophylactic or therapeutic management of experimental peripheral circulatory failure. The intravenous injection of large volumes of

one-half dilution plasma have prevented the development of shock. Whole plasma has a similar effect. The results obtained with the concentrated plasma are at best unpredictable, and are not comparable to those obtained with either of the other forms.

The fluid which is lost from the bowel contains 3 to 4 per cent protein, and it seems logical that both fluid and protein should be replaced in the same proportion. Theoretically, the injection of four times concentrated plasma might increase the plasma volume by withdrawing fluid from the tissue spaces. This assumes that such fluid is readily available. The results of these experiments indicate that with the peripheral circulatory failure of shock this extravascular fluid cannot be reclaimed in effective amounts by the use of hypertonic solutions. Fluid must be made available by parenteral injection or concentrated plasma injections will only add to the already increased viscosity of the blood. The increased efficiency of the concentrated plasma supplemented by a saline hyperdermoclysis supports this contention.

It should be emphasized that it is extremely hazardous to compare experimental results with conditions which occur in clinical practice. The type of shock studied in the laboratory is severe, and very large amounts of plasma are required to be effective. However, large amounts of dilute plasma have been useful in preventing operative traumatic shock (10). The experiments also indicate that very large amounts of plasma may be necessary in treating the patient. This has also been emphasized by Dunphy and others. If the circulating plasma volume of a patient is depleted to 50 per cent of its normal amount, the usual 500 cubic centimeter transfusion would be extremely inadequate in treatment of the profound shock. A logical argument in favor of the concentrated plasma is that clinically one deals with a well hydrated individual who has rapidly developed shock following an injury. Also that the four times concentrated

material might modify the factors leading to circulatory failure until the injury can be adequately treated. This can only be determined by extensive clinical trial.

Experimentally supporting evidence has not been found. It appears unlikely that fluid can be reclaimed by hypertonic plasma after shock has become established.

SUMMARY AND CONCLUSIONS

- 1 Experimental shock has been produced by intestinal trauma. This type of shock is characterized by a reduction in the circulating plasma volume, a concentration of the hematocrit, a decrease in the plasma protein concentration and specific gravity, and a marked decrease in total circulating protein.

- 2 The therapeutic and prophylactic value of half dilution plasma, whole plasma, and four times concentrated plasma in treating experimental shock has been compared.

- 3 Large amounts of half dilution or whole plasma are more efficient than concentrated plasma in this type of shock.

- 4 The large amount of protein lost from the circulation has been emphasized.

THE ENDOCRINE ASPECTS OF CHRONIC MASTITIS

Further Report on Rates of Estrogen Excretion and Results of Hormone Therapy

HOWARD C TAYLOR, J. M.D. F.A.C.S. New York, New York

FROM a wealth of clinical observation and laboratory experiment, it is now known that the proliferation and atrophy of the epithelial and certain of the connective tissues of the breast depend upon the rise and fall in the function of several endocrine glands. The internal secretions of the ovary are in fact, essential for the very existence of the mammary gland as an active organ. Since breast tissue is clearly a prerequisite for the development of chronic mastitis, the hormones which maintain the breast in this state are also necessary factors. Regarding this point there can no longer be any disagreement. Yet, in spite of much discussion of chronic mastitis as an endocrine disease, no one has yet succeeded in proving that this breast condition represents a specific response to any recognized type of glandular dysfunction.

The first step toward the solution of the problem of chronic mastitis is the establishment of what constitutes the essential tissue change taking place in the breast. In particular it is necessary to consider if chronic mastitis is not actually a collection of several diseases each with a distinctive morphology and each with a special set of causative factors.

CLASSIFICATION OF CHRONIC MASTITIS

Most classifications of chronic mastitis have been based on small histological sections from surgical specimens in which rather localized processes, such as cysts or papillomas, attain an exaggerated importance. In considering this disease from a functional standpoint, however it is necessary to regard the breast

as a whole and to base a classification on clinical characteristics, on the gross examination of tissue or on the study of histological sections taken outside of areas of circumscribed neoplastic activity.

From our study based on such criteria, it has appeared that there are easily distinguishable two major types of breast reaction to what might prove to be endocrine agents. (a) In the first type there may be only premenstrual pain and swelling, but usually there develops also a tender nodular induration of the outer quadrants. Gross section of such breasts reveals a dense shining white fibrous tissue. (b) In the second type there is a milky or oily secretion from the nipple with perhaps some palpable dilatation of the large ducts beneath the areola. Section reveals dilated tubules of all sizes from which may be squeezed a grayish white or brown fluid material. In previous studies efforts have been made to determine the histological basis of these two clinical types (66) and the nature of the surgical lesions arising in them (69).

TYPE 1. The histological changes in the breast in which there is only pain and premenstrual swelling are difficult to evaluate because of a dearth of surgical material from such cases. In a few sections studied there appeared to be only a loosening of the periacinar connective tissue suggestive of an increase in interstitial fluid in that area (Fig. 1). This appearance has been described as a premenstrual edema of the periacinar connective tissues and referred to by several writers. The condition of simple premenstrual pain and swelling seems however to pass directly into the next stage in which clinically detectable changes in breast structure are present.

In the breast with diffuse outer quadrant induration the most striking histological

Presented before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

change was found to be a connective tissue proliferation, which distorted the gland fields, compressing and scattering the small ducts and acini (Fig 2) In many cases, however, it appeared that there was also a proliferation of acini, giving a morphologic structure resembling adenomyosis of the uterus (Fig 3) As an accurate description of the process in the breast and to bring the terminology into harmony with that used in the pelvis, the term *adenofibrosis* for this variety of chronic mastitis seems most fitting Semb in his exhaustive pathological study of chronic mastitis adopted the term "fibroadenomatosis" indicating a conception of morphology of the disease very similar to the one here presented

TYPE 2 In the breast with secretion from the nipple (Fig 4) there was found dilatation of the ducts with amorphous material and desquamated cells in their lumens Periductal edema with collections of lymphocytes was a common finding, but diffuse fibrosis was absent The pathological process in this condition evidently takes place in quite different components of the breast structure from that in adenofibrosis and leads to correspondingly different morphologic results Clinically this condition may be called nonpuerperal lactation or galactorrhea, but in its pathological aspects it appears as duct dilatation with stasis of secretions

With both types of breast disease the areas selected for surgical excision contain, as might be expected, more complicated types of epithelial hyperplasia (Figs 5 and 6) These no doubt constitute the practical therapeutic problems, but it has been the concentration of attention on these localized, but perhaps only secondary, manifestations of epithelial activity that has caused some neglect of the generalized breast changes that might permit the study of some constitutionally effective etiologic agent

POSSIBLE FACTORS IN THE ETIOLOGY OF CHRONIC MASTITIS

Before the enumeration of the endocrine aspects of these two types of chronic mastitis it will be useful to consider two hypotheses which are, at least for the moment, tenable in regard to their cause

1 According to a currently popular view, the cause of chronic mastitis is an excessive, prolonged, or unbalanced endocrine stimulus acting principally on the epithelium Hyperplasia of the ducts and acini of the breast could, for example, be expected to result from stimulation by the estrogens, abnormal secretion, from an anterior pituitary hormone or the sudden withdrawal of an ovarian hormone If this concept were correct, chronic mastitis would be the actual equivalent of conditions produced in the laboratory by the injection of various endocrine substances

2 The breast is, however, also subject to effects produced through disturbances in its nervous and vascular systems The rapidity with which the premenstrual swelling of the breast develops each month can indeed only be explained on the basis of a vascular reaction with an increase in the fluid content of the mammary tissues Such a fluid increase may be due to the ovarian hormones, which are known to cause a general fluid retention (70) as well as a concentration of fluid in certain portions of the reproductive tract (4, 5, 78) Vascular change may also be initiated through the nervous system, as shown in recent experiments on the mammary blood volume of cattle (59) and in reported examples of sudden increase in the size of the human breast after psychic stimuli (67)

That permanent organic change in breast structure may be the result of an alteration in the chemical environment of the cells, caused by local vascular disturbances, is an easy hypothesis to offer, but difficult to prove Chronic congestion has, however, been held the cause of pathological effects in various parts of the body, but particularly in the organs of reproduction In the female it has been held responsible for the sclerotic and cystic ovary (33), for adenomyosis of the uterus (48) and for the so-called chronic parametritis (28), in the male for prostatic hypertrophy (41) Adenofibrosis is a disease arising in a related organ with morphologic features very similar to those of adenomyosis and prostatic hypertrophy

At least two theories must therefore be considered for the etiology of chronic mastitis The first asserts that the condition is the

result of abnormal stimulation of the breast, particularly of the epithelium by one of the ovarian hormones. The second view suggests that as a result of nervous and perhaps endocrine stimuli the breast becomes the seat of chronic or repeated vascular congestions, producing conditions that lead eventually to a fibrosis or an adenofibrosis in which later secondary epithelial changes of all sorts may develop. The evidence for these two conflicting views will be taken up under five principal headings.

CLINICAL CHARACTERISTICS OF CHRONIC MASTITIS

The symptoms and signs of the two types of chronic mastitis give the clinician at once some indication of the nature of the conditions.

The pain and swelling which are such important aspects of the *adenofibrosis* type have been ascribed by some writers to the premenstrual proliferation of breast epithelium (55) and by others to the distention of the ducts with desquamated cells (14). Actually there is little morphologic evidence either for a cyclical proliferation or cyclical desquamation of human breast epithelium. It seems almost certain, on the other hand that the premenstrual tension of the breast with its associated tenderness is due to a regularly recurring vascular engorgement or increase in interstitial fluids. Pain on this basis would of course be increased when fibrosis of the breast is present and the premenstrual swelling of the susceptible periacinal tissues must take place within a relatively unyielding fibrotic stroma. If an analogy is to be made with the symptoms of any pelvic condition, it must be with the congestive type of dysmenorrhea, with its characteristically premenstrual discomfort or perhaps with adenomyosis and endometriosis. None of these is now regarded as essentially an endocrine disease.

Secretion from the nipple is, however a symptom which points in a rather different direction. The source of some nipple discharge is undoubtedly local as in the instance of serous fluid coming from a duct containing a papilloma. In cases in which there is a milky

secretion from many ducts of both breasts or a discharge of semisolid, fatty material, the functional response of the breast to its natural, endocrine stimulus is closely imitated. Here then an endocrine cause seems likely from the clinical findings.

COMPARISON OF THE HISTOLOGY OF CHRONIC MASTITIS WITH BREAST CHANGES EXPERIMENTALLY PRODUCED BY HORMONES

The second point concerns the many attempts to reproduce the disease in animals by the administration of endocrine substances. With the injection of various hormones, especially the estrogens, pathological proliferation of the epithelial elements in the mammary gland certainly occurs (9 29). Some workers have insisted on the similarity, if not identity of these induced tissue changes with those of the spontaneously developing chronic mastitis of women (11 35 36 37 38). This question of course strikes at the root of the problem because if the laboratory lesions are the same as those found in human chronic mastitis, the cause of the latter disease is already known. If they are different, new factors or an entirely new hypothesis must be sought.

A systematic attempt to compare the histology of chronic mastitis with the lesions artificially produced in animals by hormone administration was recently made at the Memorial Hospital (69). Sections from 102 cases of human chronic mastitis were first studied and the lesions tabulated. For comparison the mammary glands of 163 mice that had been treated with one of four different hormone substances were examined. The essential change produced in the mice by estrogen administration was a proliferation of new acini. There was slight epithelial hyperplasia of the duct lining and sometimes dilatation of ducts with desquamation of cells and stasis of secretion. Fibrosis though reported to occur after hormone administration (2 16) was a most insignificant feature in our series of animals.

From this study it was concluded that the essential changes of adenofibrosis, which takes place to a large extent in the interstitial tissues, are not identical with those produced in the laboratory by hormone injections (Fig. 7).

Fig 1 Intralobular "edema" of the periacinar connective tissue

Fig 2 Adenofibrosis of the breast with fibrosis as the predominant process

Fig 3 Adenofibrosis of the breast (left) and, right, adenomyosis of uterus in contrast

On the other hand, effects somewhat comparable to those found in women with dilated ducts and a non puerperal secretion are producible by these means (Fig 8)

NATURE OF THE ASSOCIATED DISORDERS FOUND ELSEWHERE IN THE REPRODUCTIVE TRACT

Gynecologic investigation of the patient with chronic mastitis must yield facts of considerable significance, for it is almost certain that any constitutional agent capable of affecting the breast must have its effect on the uterus also. Thus a glandular disorder

producing chronic mastitis should cause at least disturbances of menstruation and fertility. On the other hand, were a chronic congestion resulting from nervous or hormone factors prominent in the breast disease, signs of a similar condition might also be expected in the pelvis. From previous articles reporting the gynecologic status of patients with chronic mastitis, four aspects may be selected to stress again (65, 67, 69)

The menstrual history Disturbances of menstruation certainly affect a minority of women with chronic mastitis. A decrease in

Fig 4. Abnormal secretion with duct dilatation

Fig 6. Localized duct hyperplasia in case with abnormal secretion.

the amount or duration of the menstrual flow in women with painful breasts has however previously been described by at least 7 clinicians (69). From a total of 261 patients derived from two series of published cases (67, 69) it is also our opinion that this anomaly of menstruation is significantly more frequent in patients with the engorgement/fibrosis syndrome (adenofibrosis) than in normal women of the same age groups (Table I). The significance of the scant menstruation in these cases is not clear. Beyond the simple fact of the short flow there is little reason to suppose a primary underfunction of the ovary. It is at least as likely that processes taking place in the interstitial tissues of the breast are re-

peated in the pelvis to cause a local interference with the blood supply in the uterus with a locally conditioned diminution in flow.

One point at least in regard to the uterine function of these patients is quite clear. Their endometrial patterns give no indication of any excessive hormone stimulation (67). Perhaps the most popular endocrine hypothesis offered to explain chronic mastitis is that of an excessive estrogenic and a deficient corpus luteum activity. The effects of this type of disturbance on the uterus have long been recognized as a cystic hyperplasia of the endometrium usually associated with a metrorrhagia. Yet patients with chronic mastitis are not especially susceptible to this disease nor do gynecologic patients with endometrial hyperplasia show any tendency to the development of breast disorders of this type.

In some contrast to the patients with adenofibrosis there is among the women with nonpuerperal secretion a high incidence of prolonged menstrual intervals or amenorrhea (Table II). This may in theory be interpreted as the result of a persistent corpus luteum or perhaps of periods of depressed ovarian function during which excessive anterior pituitary activity is released.

Reproductive and lactation histories. In our group of cases about a half of all patients with the adenofibrosis type of chronic mastitis have had no children (Table III) while over 80 per cent of those with nonpuerperal secretion have had full term pregnancies. On the basis of this now fairly considerable series it appear

that adenofibrosis is definitely more common in the unmarried and in those who, though married, have not conceived. The question is open as to whether the failure to bear children led to the chronic mastitis or the conditions associated with the disease predisposed to the relative sterility.

The pathology of the ovary in cases of chronic mastitis. Many of the hyperplastic or neoplastic conditions occurring in the female reproductive tract have been associated by some observer with "cystic ovaries," and among these chronic mastitis is no exception. The functional significance of such ovaries is, however, not known. In one group at least the ovary with small cysts may be quite fibrotic with a reduced rather than an increased function (33). Nothing in the appearance of the ovaries observed during gynecologic operation in women with adenofibrosis of the breast suggests a hyperfunctioning organ (67).

Organic lesions in the pelvis. The cause of breast lesions has frequently been attributed

to organic lesions in the pelvis. The most far reaching claims for this viewpoint were made by a former president of the American College of Surgeons, Dr C. Jeff Miller, who reported the cure of breast conditions following operations for fibroids, for retroversion, and for adnexal disease. Our experience has not been as satisfactory. Of 24 patients with chronic mastitis in whom gynecologic therapy for coincident pelvic lesions was carried out, 8 were apparently cured of their breast disease (65). Since this is about the proportion in whom spontaneous cures or remissions may be expected, it is improbable that such miscellaneous pelvic lesions can be held responsible for breast disease.

Nevertheless, it remains probable, unless chronic mastitis is due to purely local factors, that some equivalent process should be found taking place in the pelvic organs of reproduction. On the basis of a large series of gynecologic examinations it has appeared to us that such an

associated condition does frequently exist. This takes the form of a disease scarcely referred to in the American literature but widely discussed abroad under the name of chronic pelvic congestion (15) or chronic parametritis (26, 27, 28, 40). According to Freund chronic parametritis begins as a vascular engorgement and, if it persists, ends as a general fibrosis of the pelvic supporting structures. It is interesting that in his patients with chronic parametritis Freund described painful breast nodules, while we have found that nearly a third of the patients with the typical engorgement fibrosis syndrome in the breast exhibit the broad ligament tenderness so characteristic of the descriptions of chronic parametritis (Table IV). It is possible furthermore that some of the patients with "cystic ovaries" with supposed salpingo-oophoritis and with severe erosions of the cervix belong in this group. Were they added the clinical incidence of pelvic congestion in women with premenstrual breast symptoms might easily reach 50 per cent. It appears then that a *syndrome of which vascular engorgement and fibrosis are prominent features does often occur simultaneously in breast and pelvis*.

ASSAYS OF URINE FOR HORMONE EXCRETION

In a previous study the rates of estrogen excretion and blood level figures on 20 women

with various types of benign breast disease were presented (67). No abnormalities were found at that time which could be regarded as characteristic of any group of these cases. At least two records of similar work have been reported since that time. Wanke and Iaulsen studied the cycles of 2 cases of "mastopathia chronica" and found a low estrogen excretion. Opposite conclusions were reached by Bucher and Geschickter who made determinations of the estrogens and pregnandiol in the urine of patients with mastodysplasia and adenosis and concluded that these cases had a corpus luteum deficiency or a relative hyperestrinism.

Since our report of 1936, 9 further patients have been studied with revised technical procedures. These cases included 3 normal women, 3 with very pronounced pain and engorgement of the breasts and 3 with a bilateral secretion of a milk-like fluid.

Techniques employed in hormone assay. In each case all of the urine excreted during the cycle was collected in 72 hour lots. The original intent had been to determine simultaneously the excretion of total estrogens, of pregnandiol and of gonadotropic substances.

The estrogens were extracted with slight modifications according to the method described by Smith and Smith (6, 61). Hydrolysis was carried out first by boiling for 3 hours a 500 cubic centimeter specimen with 4 cubic centimeters of concentrated hydrochloric acid. The urine was then extracted for 48 hours with benzol and the extract represented a concentration of hundred times assayed on castrated white mice. For this purpose 6 sprayed mice primed 8 days previously were used for each injection level. A reaction was accepted as positive only when of these animals showed fully cornified smear.

to publish the results on the 80 measurements of pregnandiol that were made. With this reservation it may be stated, however, that no abnormal trends in pregnandiol excretion were evident in the group of menstruating women with chronic mastitis.

Description of results in the 9 subjects studied
Although this work was based on the study of only 9 subjects, the following histories of the 6 with chronic mastitis show that they were in each instance extreme examples of the types of disorder they were selected to represent. Changes in total estrogen excretion, if any exist for these conditions, should have been apparent in such a group.

CASES 1, 2, and 3. These were young, unmarried women without breast or pelvic disease. The menses were normal except that during the study of 1 case, an unexpected delay was encountered. The estrogenic hormone excretion in these cases for the month amounted to 3500, 4600, and 4000 mouse units, respectively. Gonadotropic substance was detected in measurable amounts at the time of ovulation in 2 of these cases.

CASE 4. R. E., admitted September 18, 1937, was a married woman of 29 years with a history of a single pregnancy, ending in a 4½ month miscarriage, 6 months before her admission to the clinic. Menstruation had characteristically been of the 21 to 24 day cycle type with long 7 day periods. Since the miscarriage there had been marked premenstrual breast pain.

The patient remained under observation in the clinic for a year, during which time she continued to complain of severe premenstrual breast symptoms associated with lower abdominal discomfort and backache, dyspareunia, and leucorrhea. A condition of anxiety dependent on home conditions was evident.

Examination of the breasts on several occasions showed them to be medium in size, dependent, very tender with a moderate outer quadrant nodularity. The pelvic examination showed that the fundus was normal in size and position, but with marked tenderness on any manipulation of it. The adnexa and parametria were tender, the cervix hypertrophied with an endocervical discharge.

Hormone assays were carried out, beginning with a menstrual period of June 9, 1938 and ending with the onset of the next period 26 days later. The total excretion of estrogens was 1282 mouse units. No gonadotropic substance was found, but death of the test animals resulted in a failure to get any record of 3 specimens.

CASE 5. J. G., admitted November 11, 1937, was a woman of 28 years, twice married. By a former husband she had had 1 child, now 11 years old, who had been successfully nursed for 7 months. A second marriage of 4 years' duration had been infertile, although no contraceptives were used. Men-

strual periods had always been normal, occurring every 28 days and lasting 6 days. A suspension of the uterus had been performed 3 years before admission.

The present illness, having its onset 8 months previously, consisted in a bilateral premenstrual pain and swelling of both breasts beginning 7 to 14 days before each period. Examination showed the breasts to be medium in size, tender with moderate nodularity of the left one and marked induration of the right. Pelvic examination showed the fundus to be normal, a little tender on motion, the adnexa, normal, the cervix, moderately eroded. During the patient's year of observation in the clinic she developed backache, premenstrual pelvic pain, dyspareunia and dysuria. Cystoscopic examination showed only a trigonitis and the urine was sterile.

Hormone assays were begun with the period of April 8, 1938, and continued for 35 days of the cycle. The total excretion of estrogens was 6030 mouse units. Gonadotropic substance was present during 2 three day specimens of the cycle, but these unexpectedly were the days immediately after the menstrual bleeding.

CASE 6. H. J., admitted December 11, 1937, was an unmarried girl of 24 years, whose periods had always occurred at 35 day intervals and been so scant as to be described by her as "negligible." There had always been moderate pelvic dysmenorrhea, but for 7 years there had been in addition very severe pain and swelling in both breasts for 2 weeks before each menstrual period.

Examination showed a rather slender girl with large breasts, diffusely thickened throughout and markedly dense and nodular in the outer quadrants. The breasts were also very tender. No pelvic examination was ever done.

Hormone assays were carried out during the cycle beginning on March 13, 1938. The total excretion of estrogens was 5085 mouse units. Gonadotropic substance was present in the specimen representing the fifteenth, sixteenth, and seventeenth days before the following period.

The patient was later treated with progesterone before her periods receiving 3 units during one month and 15 units the next. Before a subsequent period she received 150,000 units of estradiol benzoate, without affecting the breast symptoms or the amount of menstrual flow.

CASE 7. B. S., admitted January 23, 1937, was a married woman of 38 years, the mother of 2 children, ages 7 and 12. They were each nursed only 1 month on account of painful nipples. The menstrual periods formerly occurring every 28 days and lasting 4 days had stopped abruptly and without apparent cause 3 years before admission. Since that time there had been slight spotting on 3 occasions, but none during the previous year. Flushes had never developed.

For 7 years there had been a discharge from each nipple. Eight weeks before admission there had been a sudden swelling and hardness of the left

TABLE V—TOTAL ESTROGEN EXCRETION IN NORMAL WOMEN AND IN WOMEN WITH CHRONIC MASTITIS

Case	Type of Case	Total milk excretion (mg)	Avg. estrogen excretion per day in 7 June periods (micrograms)	Tabulated under days before preceding menstruation										Total	Days

Cases in which gonadotropin substance was also present

breast associated with fever. These acute symptoms had subsided but lumps had persisted in the lower part of the left breast.

Examination showed that the breasts were large and pendulous with nodular areas about both areolae. Pressure over the areolae produced milk discharge from several ducts on both sides. Pelvic examination showed no abnormalities and no evidence of trophic.

The patient was observed for over 3 years with little or no change in the breast condition. Operation for the lumps was considered on several occasions but these tended to disappear. On May 9, 1938 hormone assays were begun and continued for 30 days. The excretion of estrogens during this time was 866 mouse units, a low figure but no gonadotropic substance was demonstrable.

CASE 8. M. G. admitted January 15, 1938 as married woman of 38 with 2 children, aged 7 and 20 years. Lactation had been discontinued after months with each child owing to deficient secretion of milk. Menstrual periods had always been normal, occurring every 8 days and lasting 3 days. One abortion 3 years ago had been followed by removal of the left tube and ovary.

The present illness began 3 weeks before admission with sudden enlargement and the appearance of milk in both breasts. There had been no irregularity of the menses.

Examination showed the breasts large and pendulous somewhat tender and definitely nodular. Pressure over the areolae produced a profuse milk-like discharge and some thick casts of ducts. The pelvic examination was entirely normal.

Beginning with the menstrual period of January 3, 1938, hormone assays were continued for 28 days. The total estrogen excretion was 3683 mouse units and no gonadotropic substance was detected. This rate of estrogenic excretion was clearly in the normal range.

CASE 9. H. G. admitted May 3, 1937 as married woman of 33 years had had child 3 years before and no other pregnancies. Four years before admission (January 7, 1933) she had had gynecologic operation with removal of both tubes and the left ovary for salpingitis isthmica nodosa of the demomyoma type and small benign papillary cystadenoma of the ovary. A second operation 6 months before admission (October 28, 1936) resulted in the removal of the uterus and the remaining ovary for multiple follicle cysts. Menstruation before the first operation had been normal, occurring every 3 days and lasting 7 days and as average amount. After the first operation it became irregular with intervals of 6 to 8 weeks and duration of only 3 days. After the second operation all menstruation ceased.

From the time of her only pregnancy there had been constant secretion of little fluid from both nipples but this increased abruptly after the second operation. Also there appeared at that time some pain and considerable swelling of the breast.

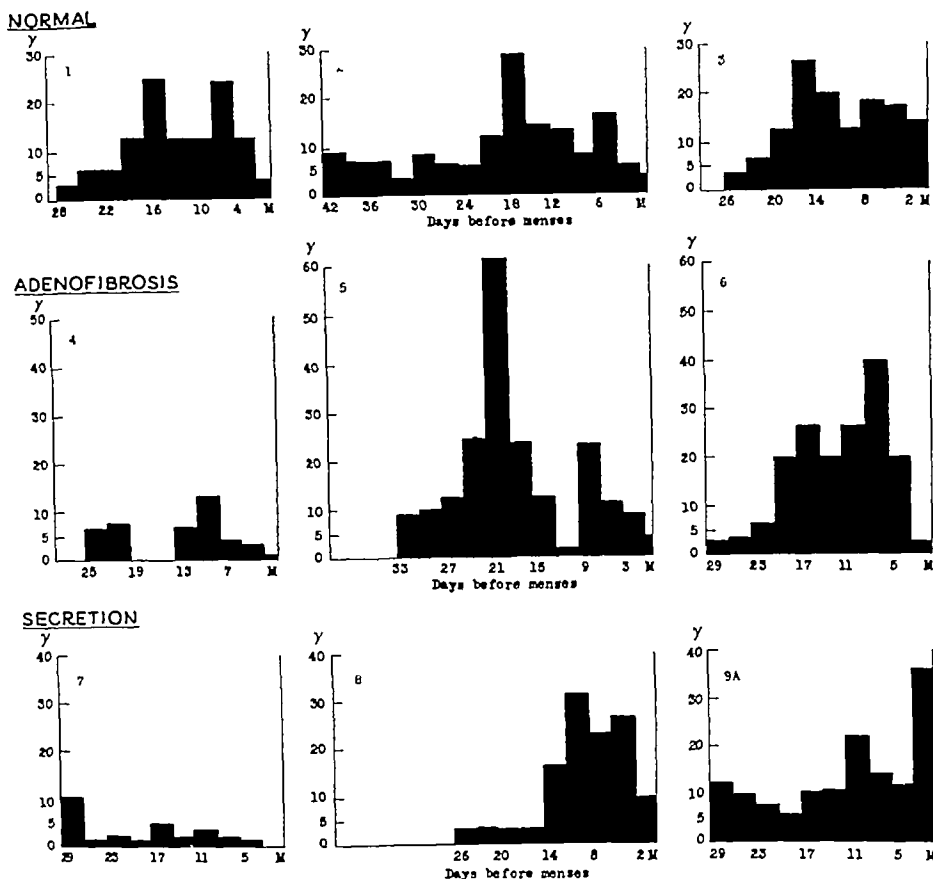

Chart 1 Total estrogen excretion in normal women and in chronic mastitis

Examination on May 3, 1937, showed the breasts to be medium in size, soft and dependent. From each breast large quantities of milk could be expressed in thin streams. Pelvic examination showed no masses in the pelvis and little evidence of atrophy. The sella turcica was later found by x ray on July 18, 1938, to be "very small and the posterior sphenoidal process thin."

Four complete sets of hormone determinations were made on this patient (Chart 2). (a) The first, carried out from March 3, 1937, to April 28, 1937, yielded 4,284 units of estrogen. Gonadotropic determinations based only on the microscopic examination of the ovaries gave 1 positive reaction. (b) Beginning May 3, 1937, the patient received 4,000 international units of amniotin 3 times a week for a month. The breasts were unaffected. Determinations of urinary estrogen from May 16 to June 16, 1937, during the period of administration suggested an actual fall in excretion. This month's urine was extracted in duplicate by 2 separate methods using benzol in the Smith and Smith extractor and ethylene dichloride in a simple stirring

apparatus. The figures for the two methods were 2,177 and 1,751 respectively. (c) Beginning on June 18, 1937, the patient received 3 injections weekly of 50,000 units of estradiol benzoate for a total of 600,000 units. Estrogen excretion rose to 17,318 units for the 30 days of this study. During this month the breasts were somewhat more swollen and tender than previously, but no diminution in secretion occurred. (d) For a few months after these injections there was little improvement and the patient complained rather bitterly of the breast pain. Then improvement set in. A further set of estrogen determinations made after 14 months and during this period of improvement showed the month's excretion to be 4,074 units, a figure almost identical with that obtained in the first month of study when the abnormal milk secretion was at a maximum.

Summary of results of hormone assays The results obtained in each of the 115 bio-assays for estrogenic hormone have been tabulated (Table V) and are shown in Chart 1. The specimens in which gonadotropic substance

were found in the urine are also indicated in the table

Certain points need to be stressed

The monthly excretion of estrogens for the 3 normal subjects ranged from 3,500 to 4,600 mouse units. Gonadotropic hormone was detectable in 2 of these women at the middle of the cycle. The normal estrogen figures are distinctly higher than those previously reported by us, the difference apparently being due to the additional step of acid hydrolysis. The close agreement of the figures for the 3 normal women is probably accidental and it would be unsafe to consider as abnormal any excretion rate within the range of 1,500 to 6,000 mouse units a month.

The first 2 of the 3 cases of adenofibrosis were married women with symptoms to be regarded as due to an associated pelvic congestion. In each the breast symptoms were of short duration, but in each changes in the texture of the breasts were present. Both women had normal menstrual cycles, and 1 had recently been pregnant. The estrogenic hormone excretion of the 2 showed a wide difference, 1,200 to 6,000 mouse units, in a single cycle. One showed gonadotropic excretion near the time of the menstrual cycle.

The third patient was of a different type being a single girl who had had scant menses and severe breast pain and swelling since the onset of her periods. No symptoms suggestive of associated pelvic congestion were present. The structural breast changes, almost certainly predominantly fibrous, were very pronounced. The estrogen excretion was 5,085 mouse units, a high figure, but probably within the normal range. Gonadotropic hormone at the mid point in this cycle might be interpreted as evidence of a normal pituitary stimulus to ovulation.

The 3 cases of abnormal secretion illustrate the extraordinary variety of clinical and hormone conditions under which this symptom may appear. All were in married women who had borne children but 1 patient was menstruating normally (Case 8). 1 had ceased spontaneously at the age of 35 (Case 7) while 1 (Case 6) had recently undergone a surgical operation with the removal of her uterus and supposedly all of her ovarian tissue. The

monthly estrogen excretion in these cases was 900 units, 3,600 units and 4,300 units, respectively. In none of these were excessive quantities of gonadotropic hormone detectable in the urine.

The third case (Chart 2) deserves special comment for three reasons. (1) The figure of 4,300 units of estrogen excretion is a most unexpected finding in a woman who had apparently suffered the surgical removal of both ovaries. (2) When estradiol benzoate to the amount of 600,000 units was given, the total estrogen excretion in the urine was significantly raised but no alteration in breast symptoms occurred. (3) When 14 months later the abnormal breast secretion had begun to diminish total estrogen excretion in the urine was at the same level as that noted when the breast symptoms were at their height. There appeared then to be no correlation between abnormal lactation and estrogen excretion or administration in this extensively studied case.

In judging the significance of these results the general value of urinary assays as a measure of endocrine function needs to be considered. It should be remembered first that when an estrogenic substance is injected intramuscularly as little as 2 to 3 per cent is recoverable in the urine. There is no reason to suppose that the several thousand mouse units of endogenous hormone which appears in the urine during a month a cycle represents any larger fraction of the total amount being produced by that individual. When contrasts of the ovarian function of different subjects are made on the basis of their urinary estrogen the assumption is evidently being made that the excretion rates have a pretty constant ratio to rates of hormone production. There is, however, little justification for assuming that this is true. The possibility that the proportion of effective estrogen, which is excreted may vary greatly in different individuals, taken with the large error inherent in the technical methods requires that very large differences in urinary estrogen be present before differences in ovarian function may be claimed. Similar comments must be made about the gonadotropic hormones whose study in the urine of nonpregnant women has been

Chart 2 Relationship of estrogen administration to rates of hormone excretion and to symptoms in a case of chronic mastitis

given considerably less trial than has the estimation of the estrogens. The significance of the absence of the hormone at the time of ovulation or its appearance on unexpected days of the cycle is unknown.

The results show then that in patients with the adenofibrosis type of chronic mastitis a wide range may be found in total monthly estrogen excretion, that the average figure is close to that for normal women, that the extremes are probably within the normal range and that typical peaks of estrogen excretion occur. In 1 case at least gonadotropic hormone appeared in the urine at the expected time for ovulation. Women with breast engorgement and adenofibrosis do not therefore display any characteristic disturbance of ovarian or anterior pituitary function, as determinable by these methods.

In the cases with abnormal secretion from the breast a wide range in the figures for monthly estrogen excretions was present. There was also room for the claim in 2 of the 3 cases that the contour of the excretion curves was abnormal in the sense of an absence of pronounced peaks in estrogen excretion.

The failure of large quantities of gonadotropic substance to appear in the urine of the 2 amenorrheic women of the group is of possible interest. Some peculiarities in hormone excretion are therefore present, as might be expected with such pronounced disturbances of menstruation. One cannot, however, on the basis of these studies be precise as to the nature of the hormone disorder in cases of abnormal breast secretion.

THE HORMONE THERAPY OF CHRONIC CYSTIC MASTITIS

The results of endocrine therapy in chronic mastitis is pertinent to the subject, since proof of the effectiveness of such an agent would be strong evidence for the hormone nature of the disease. A review of the history of hormone therapy in breast conditions is a disillusioning exercise.

Chronic mastitis has been treated by each of the new sex endocrines as they became available and, to judge from published reports, all methods have been more or less successful. Substances which have allegedly been followed by improvement include the following ova-

TABLE X.—RESULTS OF HORMONE THERAPY IN RELATION TO FREQUENCY OF SPONTANEOUS IMPROVEMENT

Type of treatment	Total cases	Pain		Nodularity		Secretion	
		Cases with the symptom	Prevalent or improved	Cases with the symptom	Prevalent or improved	Cases with the symptom	Prevalent or improved
Hormone therapy			78				
Observation only	20	16	11	13	30		
All hormones immediately results		69		66			
All hormones results after years	86	61	37	64	30	1	15

patients about three-quarters reported improvement or cure following their supposed treatment.

The explanation of these somewhat surprising results is simple enough. The pain and premenstrual engorgement are symptoms varying in a given woman from month to month. The patient with this type of breast disease almost invariably applies to a physician in great anxiety at a time of exacerbation of symptoms. It is almost a certainty that from the peak of symptoms which brought the patient to the clinic some amelioration will occur in immediately succeeding months.

It has been our experience, however, that when fibrotic change has developed in the breast to any marked degree although it may become less painful or even symptom free some evidence of nodularity will persist almost indefinitely. The secretion of milky or oily material from the nipples is also a condition subject only to gradual change. It lasts as a rule for many months and even well into the menopause.

Effect of injections of various hormones in chronic mastitis. Between 1932 and 1939, 73 cases of chronic mastitis have been treated in the Memorial Hospital Breast Clinic by injections of some hormone preparation. The

Although many of these patients were treated some time ago actual improvement should be made to Dr. Max Gilbert of the Achern Corporation for extended treatment (progesterone B) and testosterone propionate (androgen) to Dr. J. A. Marshall of E. R. Squibb and Sons for supplies of estrone (menometron), gonadotropic hormone (vitamin B₁₂ solution) and prolactin.

TABLE XI.—HYPOTHETICAL SCHEME OF RELATIONSHIP OF TYPES IN CHRONIC MASTITIS

	Type of inflammation	Type of inflammation
	Pre-menstrual engorgement, Mastodynia	Complicated secretory, Glandular
Stage of functional disturbance	Pre-menstrual engorgement, Mastodynia	Complicated secretory, Glandular
Stage of diffuse tissue changes	Nodular induration of outer quadrants, Fibrosis, Adenofibrosis	Diffuse induration, Stage of secretory, Periductal inflammation
Stage of localized secondary neoplasms	Adenomatous proliferation of the small ducts and acini, Cysts	Hyperplasia of ducts, Proliferation, Cysts
Causing factor	Ovarian hormone, Nervous factor, Vascular factor	Ovarian dysfunction, Primary dysfunction

substances employed included the following: various preparations of estrogens, in doses ranging from less than 3,000 to more than 100,000 international units a month; estradiol benzoate in doses up to 600,000 units a month; lactogenic substance (prolactin), gonadotropic luteinizing substance, corpus luteum and testosterone propionate. The distribution of cases, the dosage employed, and the effects of the therapy both during and after treatment are given in detail in Tables VII, VIII, and IX.

From a study of Table VIII it appears probable that some improvement in the pain of adenofibrosis occurred during the actual months of administration of testosterone propionate and perhaps also of prolactin. Re-evaluation of the cases after 2 years, however, showed that in no hormone group was the improvement in the pain or nodularity significantly greater than in the control series (Tables IX and X). There was indeed a possibility that the estrogens actually retarded recovery since the proportion of improved cases in the groups so treated was actually lower than could have been anticipated from spontaneous remission alone.

In regard to the symptom of abnormal secretion one must note that the figures point to an improvement in one-third of the hormone treated cases, 2 years after therapy was given. On the other hand evidence for an immediate effect was slight, a point em-

phasized by the failure of 600,000 units of estradiol benzoate to suppress the secretion in Case 9

Effect of radiation of the ovaries In contrast to the results obtained when stimulating hormones are employed, are those obtained when the ovaries are removed or radiated. The cases, in which such therapy for breast disease is justifiable, are of course exceptional. Our experience with 18 cases so treated (68) show that pain is invariably cured or improved and the nodularity usually somewhat lessened. Abnormal secretion, on the other hand, is very slightly affected for some time.

Summary on Therapy From this experience it is our opinion that glandular therapy up to the present time has been of no benefit in the treatment of chronic mastitis. No hormone we have used to date has produced permanent results exceeding the anticipated rate of spontaneous improvement. The estrogens in particular are probably contraindicated in view of their capacity to cause epithelial proliferation and breast engorgement. The androgens and perhaps progesterone may produce temporary improvement by suppressing ovarian function, but there is no reason to suppose that these results will be permanent. The single established fact in regard to hormone therapy is that abolition of the ovarian function by castration will cause cessation of pain in almost all cases of adenofibrosis and a slow but definite disappearance of the nodularity.

SUMMARY AND CONCLUSIONS

In Table XI is presented a scheme of the relationship of different types of so-called chronic mastitis. It is presented as a hypothesis which seems best to explain the facts now available on this subject.

There are two types of abnormal reaction in the breast which appear to be the result of hormonal or other constitutional agents. Each appears in a purely functional stage, but on the basis of each characteristic organic changes may develop.

Type 1 (adenofibrosis) is at first characterized only by premenstrual pain and swelling, which seems almost certainly to be due to vascular engorgement or increase in tissue fluids. A diffuse induration of the outer

quadrant of the breast due to a proliferation of the connective and epithelial tissues is, however, found in most of these cases and indicates a second stage. A relationship between the excessive premenstrual engorgement and the development of the diffuse fibrosis is suggested by the almost invariable association of the two conditions. Isolated nodules of epithelial activity produce the lumps that require excision but are perhaps purely secondary, localized phenomena developing on the basis of the general adenofibrosis.

Among causative factors it is evident that an actively functioning ovary is a prerequisite to the development of this disease. Yet the infrequency of changes in the cycle of menstruation, the usually normal endometrium, the inability of various workers to agree on any abnormality of hormone excretion and the apparent failure of all endocrine therapy (except castration) speak against any simple quantitative abnormality of sex hormone physiology.

The clinical evidence for an excessive premenstrual vascular reaction in the breasts of these patients is unmistakable and with this are often found clinical signs of a similar disorder in the pelvis. A general nervous instability often with local hyperesthesia of the breast is commonly present in these patients. Many signs point therefore to the need of studying these nervous and vascular factors to determine whether through such agents an abnormal environment may be set up about cells of the breast which could lead to the organic changes of adenofibrosis.

Type 2 (nonpuerperal secretion) in its functional stage is characterized by a milky discharge from the nipple and histologically perhaps by slight hyperplasia of the acini. There soon develops a condition in which dilated ducts become filled with desquamated cells and stagnating secretion. That periductal inflammation, cysts, and hyperplastic or metaplastic changes in the duct lining may result when such a condition is of long standing seems probable.

In many cases of this type an endocrine disturbance in the form of grossly disturbed menstrual cycles is quite evident. Atypical curves

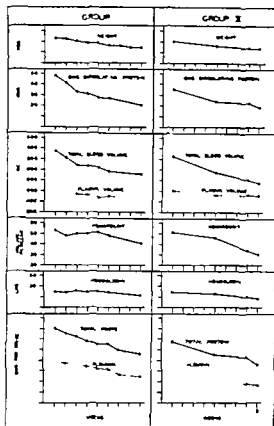

Chart 1. A cage changes in weight, total circulating protein, total blood and plasma volume, erythrocyte volume per cent (hematocrit), hemoglobin, total serum protein and albumin fraction concentration in groups of 4 dogs each during 8 weeks on low protein diet.

Changes in blood volume after intervals of 30 to 40 minutes were calculated from variations in the erythrocyte volume per cent. Hematocrit determinations were made on heparinized blood with the Winthrobe tube.

Serum protein determinations were made by the micro-Kjeldahl procedure. Albumin and globulin were separated by the use of 25 per cent sodium sulphate. Nonprotein nitrogen determinations were made according to the Kock McMeekin method (7) modified for reading with the photoelectric colorimeter (9). All determinations were made in duplicate.

Blood for plasma transfusions, withdrawn from a group of donor dogs, was prevented from clotting by the use of heparin except in

Chart 2. Change in weight and erythrocyte volume per cent (hematocrit) and total blood and plasma volume per unit of body surface in each of dogs during 8 weeks of protein depletion.

one instance when sodium citrate was used. Plasma, removed by centrifugation and stored in liter flasks at 0 degree to 4 degrees C. until ready for transfusion was analyzed for total protein, albumin and globulin concentration. The total serum protein concentration of the pooled donor plasma varied from 5.6 to 6.3 grams per cent.

RESULTS

Effect of low protein diet on blood volume and serum proteins. In order to study the changes in the weight, total circulating protein, total blood volume, plasma volume, hematocrit, hemoglobin, and both the total and the albumin fraction of the protein concentration after the inauguration of the protein free diet, a group of 4 dogs (group I) was studied at weekly intervals until there was a marked hypoproteinemia. The results are shown in

Chart 1 from which it is noted that there is a gradual decrease in all the values over a period of 8 weeks. It is apparent that the decrease in the total protein concentration is due to the diminishing albumin fraction.

To eliminate excessive bleeding as a factor in the development of hypoproteinemia another group of 4 dogs (group II) also shown in Chart 1 was studied at monthly intervals. It was found that the development of hypoproteinemia and changes in blood volume were similar to those seen in group I. In 2 dogs (Chart 2) total blood and plasma volumes were calculated on the basis of 100 square centimeters of body surface area (5). The plasma volume decreased slightly with the development of hypoproteinemia and reduction in the absolute plasma volume. By these same methods of calculation the total blood volume decreased proportionately with the development of anemia and a decrease in the absolute plasma volume.

Effect of plasma transfusions on blood volume and blood proteins in hypoproteinemic dogs. Two hypoproteinemic male dogs were given volumes of plasma calculated theoretically to restore the serum protein level to a normal value of 7 grams per cent. The plasma was injected into the jugular vein with a syringe and the entire amount was given in about 10 minutes. These animals were continued on the low protein diet during the period of observation which lasted a week.

The most striking effects (Chart 3) were the immediate but transient increases in the total blood and plasma volumes, both returning to the pretransfusion levels within 3 days. The injected plasma exerted a diluting effect as shown by the hematocrit values. The protein concentration and total circulating protein of the sera showed only a comparatively small rise despite the large amounts of plasma injected.

A study of the serum proteins and blood volumes after small daily transfusions of plasma for 2 weeks was made in 5 hypoproteinemic dogs (Chart 4). Analyses were made at intervals of 18 to 24 hours after the preceding transfusion.

A single daily 50 cubic centimeter transfusion of plasma was followed by a gradual

Chart 3. Immediate and late effects of massive plasma transfusion upon plasma volume per kilogram of body weight, hematocrit, total blood and plasma volume, total circulating protein, total serum protein and albumin fraction concentration in two hypoproteinemic dogs. — No. 1, given 220 cubic centimeters of plasma. TP = 5.37, A/G = 1.05. — No. 2, given 215 cubic centimeters of plasma. TP = 6.16, A/G = 1.44.

increase in the serum protein concentration in 3 dogs. At the end of the experimental period there were increases of 20, 23, and 58 per cent above the initial hypoproteinemic level. The effect of removal of about 120 cubic centimeters of blood in each animal for analyses during the 2 weeks period cannot be adequately gauged. It would seem that without this withdrawal the actual increase in protein concentrations might have been appreciably greater. The absolute plasma volume showed no change in 2 animals and increased 12 per cent in 1 dog at the end of the experiment. From the percentage concentration of serum proteins and the plasma volumes, it was pos-

Chart 4. Effect of one or two small (50 c.c.) plasma transfusions daily upon the serum protein concentration of 5 hypoproteinemic dogs.

sible to calculate the total circulating protein these values were 22, 40 and 60 per cent respectively above the pretransfusion levels.

Two hypoproteinemic dogs (Chart 4) were transfused twice daily with 50 cubic centimeters of plasma. The increases in serum protein concentration were 57 and 75 per cent above the initial values. The absolute plasma volumes of these 2 dogs increased 15 and 25 per cent, respectively. The calculation for the total circulating protein showed that there was an increase of 91 and 137 per cent, respectively in these animals. The total blood volumes in these 2 groups of animals decreased during the period of experimentation due to the increasing anemia. Plasma volume per unit of body surface increased slightly with the rise in serum protein concentration in both groups of dogs (Chart 5).

EVALUATION OF STUDY

The changes occurring in serum protein in 8 dogs maintained on a protein free diet are similar to those previously reported by Weech and his co-workers. These investigators described a gradual decrease in the plasma albumin and an accompanying increase in plasma globulin. In the present experiments, it was found that the albumin fraction decreased but that there was no consistency in the behavior of the globulin fraction in the

Chart 5. Effect of one or two small (50 c.c.) plasma transfusions upon plasma volume per unit of body surface area.

individual experimental animals. The decrease in the albumin globulin ratios was due to the decrease in the albumin concentration rather than to the increase in globulin concentration.

A number of investigators (4, 14, 17) have associated a decrease of the plasma albumin concentration with a proportionate drop in plasma volume. There was no attempt made by these authors to determine the effect of weight loss by correlating plasma volume changes per unit of body weight or body surface. In the present experiments the plasma volume showed only a slight reduction per unit of surface area despite the loss of weight and the decrease in plasma albumin.

Weech demonstrated that the protein concentration of a hypoproteinemic dog could not be returned to normal by a single massive transfusion of plasma. His work has been confirmed in these experiments. In addition accurate determinations indicated that the blood volumes in these animals were only temporarily increased after transfusions of comparatively large amounts of plasma. From the work of other investigators (3, 19, 27) it appears that plasma proteins can be utilized or stored in animals that have undergone protein depletion. Hence it is not surprising that transfused plasma given in single large amounts did not appreciably increase the serum protein concentration in hypoproteinemic dogs.

Daily single plasma transfusion in small amounts was responsible for a moderate in-

crease in the serum protein concentration of hypoproteinemic dogs. More frequent transfusions (twice daily) produced a marked increase in the protein concentration. Despite the rather marked increases in serum protein concentration, changes in plasma volume, both absolute and per unit of body surface were relatively slight.

SUMMARY AND CONCLUSIONS

1 The protein concentration, total blood volume, and plasma volume were determined in dogs made hypoproteinemic by feeding an essentially protein-free diet. There was an appreciable decrease in the blood protein and volume on such a diet. Plasma volumes calculated on the basis of body surface area also decreased during the depletion period.

2 Single plasma transfusions, calculated to restore the serum protein concentration of these hypoproteinemic dogs to normal, were ineffective.

3 Serum protein concentration was effectively increased by small plasma transfusions given once or twice daily.

4 There appeared to be a relationship between serum protein concentration and plasma volume, both absolute and per unit of body surface area.

There was an appreciable decrease in the blood protein and volume on such a diet. Plasma volumes calculated on the basis of body surface area also decreased during the depletion period.

2 Single plasma transfusions, calculated to restore the serum protein concentration of these hypoproteinemic dogs to normal, were ineffective.

3 Serum protein concentration was effectively increased by small plasma transfusions given once or twice daily.

4 There appeared to be a relationship between serum protein concentration and plasma volume, both absolute and per unit of body surface area.

AN EVALUATION OF BLOOD AND BLOOD SUBSTITUTES

MARK M. RAVITCH, M.D. and ALFRED BLALOCK M.D. F.A.C.S. Baltimore Maryland

WARS have served as the incentive for many advances in surgery. The uses of blood and substitutes for blood have received particular attention in wartime and a number of important contributions have resulted. The employment of stored or preserved blood and of plasma was recommended during the last world conflict, but the suggestions did not receive the attention which they merited. These remarks are not meant to imply that the need for blood and its substitutes is peculiar to warfare. The increase in the numbers of operations and of injuries in civil life has extended greatly the indications for the employment of intravenous injections in the prevention and treatment of peripheral circulatory failure. The realization that shock should be recognized and treated in the early rather than in the fully developed stage has resulted in the saving of many lives.

The importance of the subject under consideration is demonstrated by the fact that one of the first of the studies which were requested of the National Research Council by the Medical Corps of the Army and Navy was on the use of blood and blood substitutes. At the initial meeting of this committee more than a year ago Dr. W. B. Cannon mentioned the need for improvements in methods for preparing preserving and administering solutions which are already available. In addition, he pointed out the desirability of preparing fractions of blood from man and animals which might be as good as or superior to these fluids. The brilliant work of Dr. Edwin Cohn and his group has resulted already in the separation of human albumen which for some purposes appears to offer many advantages.

In any choice of a blood substitute one must have clearly in mind the particular function of the blood which requires reinforcement. These functions, all interrelated, may

be separated for purposes of discussion. They include oxygen transport by the red cells, osmotic pressure maintenance by the plasma proteins, coagulation through the prothrombin-fibrinogen mechanism, nutrition with special reference to the rôle of the plasma proteins, participation in body response to infection through complement and circulating antibodies, and phagocytosis by the leucocytes.

It is at once obvious that whole blood, and preferably fresh whole blood, is the one fluid which will fortify the circulating blood in the performance of all of its functions. While we shall discuss the relative advantages of given substitutes in various conditions it must be remembered that in most conditions all substitutes for whole fresh blood are inferior. It is doubtful whether under any but a few special circumstances any of the substitutes is superior to whole blood. Even in the hemoconcentration associated with severe burns the objection to the use of whole blood has probably received more emphasis than it deserves. If the total blood volume is maintained at an essentially normal level pronounced degrees of hemoconcentration are tolerated remarkably well.

While in a given instance replacement of blood because of disturbance of a single function is the primary concern several of the functions are probably simultaneously affected. In addition, when dealing with wounded men or with patients on the operating table one must realize that treatment is being given to a person who will not be restored at once to full health. Problems of nutrition, hydration, and infection will have to be met, and the handicapped organism, especially with the additional burdens imposed by wartime conditions, may have difficulty in replacing water, proteins, and perhaps even the formed elements of the blood. Any foreign substance such as acacia or pectin, however valuable its immediate effect must either be excreted with more or less rapidity

in which case its specific effect is temporary and it serves not at all as a real replacement for the depleted stores of protein and circulating cells or else it is deposited in the tissues, where it may be positively harmful. Nevertheless, numerous practical considerations force us to be satisfied with substitutes for whole fresh blood, and for many purposes some of these substitutes are so efficacious that the loss is not great. Thus, almost all of us now use refrigerated blood because of its convenience and availability, reserving the use of fresh unstored blood for special conditions.

In the evaluation of blood substitutes the qualities for consideration are first of all effectiveness and safety. Regardless of all else, our substitute must do its job well without adding unwarranted hazards. Ease and cost of preparation in adequate quantity, simplicity of administration, and capability of storage and transportation are the secondary qualities which determine the choice of a substitute from among those of equal value and innocuousness.

Oxygen transport Whole human blood is the most effective agent for the transport of oxygen. Blood—fresh, briefly stored, or preserved with added glucose—is the only material available for clinical use which will adequately subserve this function. The older the blood, the fewer are the red blood corpuscles which are intact and the shorter is their expected life in the blood stream of the recipient. Although in stored blood there is little change in this direction during the first week. Preservation of blood with added glucose lengthens the life of the cells and retards the increase in fragility, but has the disadvantages of dilution and large bulk. In shock, when inefficiency of the circulation due to lowered plasma volume interferes with the oxygen carrying power of the blood, the administration of serum plasma, or any other materials, thereby correcting this condition, at least temporarily results in improved oxygen transport. All of us have seen patients getting along remarkably well with a red blood cell count of 1,000,000 as a result of gradual blood loss. The plasma volume in such cases will be about normal. In acute severe hemorrhage, how-

ever, most patients will not tolerate the loss of even one-half of the total blood volume unless replacement therapy is employed. In other words, although one-half of the red blood corpuscles may still be present in the vascular bed the patient may yet succumb because of the lowered plasma volume. On the other hand, the early administration of plasma or serum following severe blood loss will render more effective the reduced number of corpuscles remaining and recovery will usually result if the bleeding has been controlled. In such circumstances plasma or serum is not so efficacious as whole blood, but the results are usually satisfactory.

In anemia, then, acute or chronic, whole blood, as fresh as possible, is best. In acute hemorrhage any effective blood substitute may be used while whole blood is being obtained or while hemorrhage is being arrested. To treat a patient with a ruptured ectopic pregnancy or a bleeding gunshot or stab wound with plasma or serum alone is to run unnecessarily the risk of increased hemorrhage due to a rise in blood pressure before bleeding has been arrested. If the hemorrhage can be promptly controlled, this treatment may be safe. It is dangerous to treat vigorous gastric bleeding with plasma or serum unless preparations for operation are under way. Even after the hemorrhage has been controlled the resultant severe anemia will handicap the patient and necessitate blood transfusion. When blood is available it is much better to give it at once. And it can now be made constantly available, in all hospitals at least.

Recently Amberson in Baltimore, Cunnam in New York, and O Shughnessy in England have aroused interest in the use of hemoglobin alone. Pure crystalline human hemoglobin can be prepared and maintained in stable solution or lyophilized if desired. Because of the efficiency of extracorporeal hemoglobin in carrying oxygen, cells can be kept alive 24 to 36 hours on icline hemoglobin after all of their red blood cells have been removed. In addition this hemoglobin exerts an osmotic effect several times greater than that of the plasma proteins. Human beings have been given large doses of hemoglobin intravenously with no ill effect. This employment of hemoglobin

globin is particularly attractive in view of the volume of red blood cells discarded in the preparation of plasma. The injected hemoglobin however soon alters to inactive methemoglobin and in being excreted throws an added burden on the kidneys.

Maintenance of osmotic pressure of the plasma proteins. Shock represents the chief acute condition requiring the reinforcement of this function of the blood. Again except perhaps in burns whole blood is superior to all other substances. It treats the shock as effectively and at the same time provides red blood cells and, if fresh enough, white blood cells and platelets as well. The exigencies of medical practice however and especially of military medical practice have been responsible for the search for suitable substitutes.

Both plasma and serum are approximately equally effective. There is a somewhat greater likelihood of unfavorable reactions when serum is employed. Plasma contains fibrinogen which serum lacks. They are prepared and administered with about equal ease. Plasma is more conveniently employed in connection with blood banks than is serum but serum is more readily run through bacteriological filters, if that is desired. Both are capable of long storage and transportation—liquid frozen, or dried. As to the relative merits of the substances in the various physical states, liquid plasma is most readily administered frozen plasma preserves the various protein elements best and dried plasma is most conveniently transported. Dried plasma requires expensive and elaborate equipment for large scale production. Liquid plasma offers least resistance to bacterial growth frozen plasma must be rapidly thawed in a water bath at 37 degrees C and dried plasma must be regenerated with distilled water suitable for parenteral use. All have the advantage over blood of being capable of long storage and of not requiring matching before administration. In this last respect they are probably safer than blood, although the possibility of bacterial contamination offsets the advantage of freedom from incompatibility reactions. Liquid or frozen plasma seems best suited to civilian use or to military use on a fixed battlefield, as in England at

present. Dried plasma finds its chief employment in shipment to foreign stations and on naval vessels.

Some workers in the field have put forth as an advantage of the dried material the fact that it can be redissolved in a small volume of water producing a hypertonic solution which, when injected into the blood stream, exerts a powerful osmotic pressure drawing fluids from the tissues and reversing the mechanism of shock as it is stated. Unfortunately most patients in shock—and this is particularly true of soldiers wounded on the field of battle and of burned patients—are not only already dehydrated or in need of fluids, but are entering on a period of their illness when water intake will be of great concern so that it would be well not to increase the tissue water debt at the start. However the idea of administering the proteins from a pint of blood in a single 50 cubic centimeter injection is very attractive and offers possibilities for treatment of shock far forward in the battle zone.

It has been found by Dr. Cohn and his associates at Harvard that human plasma can be fractionated into its various protein constituents, which, reduced to pure crystalline states may be redissolved, forming stable nonviscid solutions which flow readily through small needles. Albumen the largest fraction, is the one which exerts the greatest osmotic force. Hypertonic solutions of albumen obtained from alcohol fractionation of human plasma have been employed in a small number of cases and seem extremely effective in the treatment of shock. Unlike the substances which will next be discussed the albumen thus injected is utilized by the body. Production is said to be cheaper and simpler than the preparation of dried plasma, but quantity production is similarly limited by the difficulties in the procurement of large quantities of human blood. Bovine albumen, prepared by the same method, solves the problems of quantity and cost but thus far the bovine albumen has not been free from a small fraction of globulin. The occurrence of sensitivity reactions in human beings given this material has been attributed to this fraction. If bovine albumen which in itself seems not antigenic

can be obtained in sufficiently pure form to be safe, a very nearly ideal plasma substitute for military use and for some civilian uses will have been found.

Human fluids other than blood and its derivatives have been employed. While pleural fluid, and even that occurring in a case of chylothorax, has been safely injected intravenously, most attention has been paid to ascitic fluid. Of this fluid it may be said that it is similar to plasma, but contains roughly half as much protein and is therefore half as effective for most conditions. It is obtained cheaply but in very limited quantities, and the source of supply is undependable. Experience with it is still small. Earlier workers reported frequent reactions. More recent work, using citrated ascitic fluid, seems to have decreased the incidence of reactions. The fluid can be dried, but it seems a waste of time to start with so dilute a fluid. If it can be shown to be free from danger of reactions, it may form a useful source of additional stores in hospitals.

Attempts have been made to use whole beef plasma. Wangenstein in Minneapolis and Muether in St. Louis have demonstrated that some patients tolerate large masses of bovine plasma intravenously although with frequent sensitivity reactions. During the first World War Brodin and St. Giron employed horse plasma in 500 cubic centimeter quantities in several instances without untoward results. It seems unlikely, however, that whole plasma from other animals can be made safe for human use, although suitable purified protein fractions are a distinct possibility.

Animal protein substances of other origins have been proposed, the latest being gelatin which is derived from fish bladders. Dried fish bladders, sold commercially to brewers, when suitably treated yield a readily soluble powder. Injected into dogs the solution is effective in the treatment of shock, causes no reactions, and is not antigenic. Its use in human beings has not been reported, and here as with other foreign substances we must know that the material is not antigenic and that preferably the protein is utilizable by the human organism and is not treated as a foreign substance to be excreted.

Substances of plant origin have also been investigated. Acacia, the complex carbohydrate derived from the gum of certain shrubs of the genus *Acacia*, is the chief of these. It was suggested as a blood substitute as far back as 1906 and was first administered to human beings in 1917. It has been proved to be fairly effective in the treatment of shock, but immediate unfavorable reactions have been too frequent and doubt has been thrown on its eventual fate in the body. It is apparently stored in the liver for long periods and impairs the function of the liver in protein formation. It has also been said to combat the treatment of shock by interfering with oxygen absorption by the red blood cells. For these reasons, and because it fails to supply the whole organism with the additional protein usually required in hemorrhage and in traumatic shock, it has not found much favor.

More recently, common citrus fruit pectin, commercially supplied for the making of jellies, has been prepared by Hartmann and his coworkers for use as a plasma substitute. Only 8 clinical instances of its use are reported, and in at least 1 a chill occurred. It is apparently nonantigenic in guinea pigs, rabbits, and dogs. In the dog it is largely excreted in the urine in the first 48 to 72 hours. Like acacia it is a foreign material of no demonstrable value to the body after the effect of the initial injection has disappeared. Least effective of all for the reinforcement of the oxygen-carrying power of the blood or the osmotic pressure maintenance are the solutions of the crystalloids. Their benefit is purely temporary. In hemorrhage, unless bleeding has been arrested and shock is mild, they may increase blood loss and wash proteins into the tissues as well. We all recall in the recent past, before the ready availability of blood and plasma radically altered the treatment of sudden shock or hemorrhage, the very brief period of benefit from the injection of solutions of glucose or sodium chloride, except in cases of mild shock in which the precipitating factor had been discontinued.

Blood coagulation. The effect on blood coagulation of the various substitutes has not been comparatively studied. Platelets survive in stored blood for 2 to 5 days. Fresh whole

blood or blood refrigerated for a short time probably increases the clotting power of the recipient's blood and this is probably true of plasma as well. It is not likely that any preparations not derived from human blood will have such power.

Nutrition In speaking of the nutritive rôle of the blood we are now concerned chiefly with its protein content. While the proteins of the blood are formed elsewhere than in the blood stream it has been shown that they may be utilized in turn by the body for storage in the tissues. In conditions of chronic hypoproteinemia the administration of whole blood as long as the hemoglobin is low (as it usually is in these conditions) followed by the administration of plasma or serum is fairly efficacious. Since as a rule, low plasma proteins are associated with depleted protein stores in the tissues, great quantities of plasma must be administered intravenously before any effect is reflected in the level of the plasma proteins. In conditions of starvation, as in esophageal or gastric obstruction, some improvement may be achieved, but will be maintained only if normal alimentation is restored. In nephrosis and cirrhosis, although alimentation may be unimpaired, the continuing loss of proteins makes the problem more difficult. Amino acids injected intravenously (Elman) have proved their worth in supplying the body with building stones for the formation of tissue and blood proteins when adequate protein cannot be taken by mouth. Whipple and Madden have produced digests of casein by pepsin which are not split as far as the amino acid stage and which when administered intravenously will maintain

dogs in positive nitrogen balance indefinitely.

Infection We can expect only whole blood plasma, and serum to supply complement and immune bodies. Any blood substitute which supplies utilizable protein will indirectly aid in antibody formation. Human globulin has been purified as has albumen, and could perhaps find some use in this regard. Substances of plant origin are of no immunological value and acacia, by interfering with the regeneration of plasma protein in the liver may be actually harmful.

Phagocytosis Significant numbers of effective leucocytes can be supplied only in fairly fresh blood. Leucocytes decrease 50 per cent in numbers in 24 hours and phagocytic activity of those remaining drops after 72 hours, is slight in 5 days and absent in 7

SUMMARY

It is obvious that the ideal in replacement therapy is the administration of fluid of the same composition as that which has been lost—whole blood for whole blood and plasma for plasma. The employment of whole blood is rarely contraindicated except in instances of extreme hemoconcentration, such as that which may occur following severe burns. Plasma and serum have the advantage, particularly in emergencies, that compatibility tests are not necessary and delay in treatment can be avoided. Preliminary observations indicate that purified human albumen is a safe and effective substitute for plasma. The problem of providing blood substitutes in large quantities will be greatly simplified if nonantigenic fractions of animal plasma proteins can be prepared.

STAPHYLOCOCCUS SEPTICEMIA

Observations Relative to the State of Hydration in the Dog and in Man

CARROLL H LONG, M D, M S (Surg), Johnson City, Tennessee,
ALFRED B LONGACRE, M D, New Orleans, Louisiana

THE therapeutic problem presented by Staphylococcus septicemia remains a pressing one, in spite of the remarkable advances made in recent years through the development of chemotherapy and the widespread adoption of a physiological approach to therapeutics. The controversy which still exists concerning the efficacy of early or late surgical intervention in acute hematogenous osteomyelitis is characteristic of the confusion in this field and an indication of the fundamental nature of the unsolved problems.

Reports of various investigators stressing the importance of adequate fluid balance in the treatment of burns, intestinal obstruction, and various other acute and chronic surgical diseases, suggested the possibility that fluid imbalance in acute infections may be a factor influencing prognosis. Accordingly, an investigation was initiated having as its object the determination of some of the changes occurring in hydration during Staphylococcus septicemia.

No careful observations on hydration in the toxic phase of staphylococcus infections have been reported. A few fragmentary references indirectly bearing on the matter have been gathered. Webb and Korfmacher concluded that acute infections produce comparatively mild or temporary changes in serum proteins, of total protein, a normal or increased globulin and a decreased albumin level. Jones and Eaton in discussing nutritional edema stressed sepsis as one of the important factors in the causation of postoperative edema. Curphey and Orr made the same observation and stated

that edema was most frequently associated with starvation accompanying an acute infection such as peritonitis. Shumen and Jeghers in their discussion of the value of routine blood protein determinations listed fever as one of the causative factors of hypoproteinemia.

The importance of adequate fluid balance has been more adequately stressed in the study of other surgical diseases. The present day conception of normal water exchange, particularly as regards its clinical application in surgery, has been emphasized in the work of Coller and Maddock and their associates (4, 5, 6). They have shown that the daily maintenance requirements of fluids for the healthy adult is about 3500 cubic centimeters and that the need may be greater with increased metabolism or abnormal losses of body fluids. This investigation drew attention to the necessity for maintaining an equilibrium of electrolytes in the blood and pointed out the dangers of inadequate or excessive administration of sodium chloride.

Jones and Eaton (11, 12) first called attention to nutritional edema as a problem of clinical surgery. In 1933 they reported observations in 34 surgical patients, having critically low serum protein levels following surgery, in most of whom edema occurred. Subsequently, they showed experimentally that postoperative edema occurred following procedures frequently used in patients. It was their opinion that the production of edema was dependent chiefly upon nitrogen starvation and other forms of malnutrition in association with such factors as excessive intake of water and sodium chloride, profuse surgical drainage, general effects of sepsis, massive hemorrhage, or renal dysfunction. They produced experimental evidence that water can accumulate to a striking degree in any of the parenchymatous organs as well as

From the Department of Surgery, Tulane University of Louisiana, New Orleans.
Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Boston, November 1-2, 1941.

In the subcutaneous tissues and that all of the body functions may be greatly retarded by such an occurrence. Ravdin and his associates showed a definite relation between intestinal and gastric emptying times and the level of plasma protein. They pointed out that the edema of trauma after gastrointestinal anastomosis may be accentuated by a lowered plasma protein level to such an extent that an obstruction due to a technical defect in the anastomosis is mimicked. They further emphasized the effect of hypoproteinemia in decreasing the proliferation of fibroblasts and in producing a tendency to wound disruption after abdominal operations.

Shumen and Jeghers, in recommending study of the plasma proteins as a routine procedure for every patient, pointed out the importance of hyperproteinemia as well as of hypoproteinemia. They called attention to the value of the plasma protein level as an indication of liver reserve and particularly stressed its importance in hyperthyroidism as a means of anticipating and avoiding post-operative crisis. In routine tests on 320 patients they found that edema was present in 23 per cent of the 81 patients whose plasma protein levels fell below 6.00 grams per cent. Kormacher also emphasized the relation of the plasma protein level to the severity of hyperthyroidism and stated that levels of total protein below 6 grams per cent or of albumin below 3 grams per cent are probably indicative of hepatic damage and are reasons for performing thyroidectomy in stages. In his opinion plasma protein estimations offer a definite prognosis in obstructive jaundice, since extensive liver damage is made evident by marked reversal of the albumin-globulin ratio.

The study of the rapid shifts in fluid balance occurring after extensive burns has brought to light the important rôle played by the plasma proteins in these physiological changes. Elkinton, Wolff and Lee in a study of 5 cases of severe burns, emphasized the information which is available at the present time. After a 25 per cent burn as much as 53 per cent of the total plasma volume may disappear from the circulating blood within 40 minutes, and the loss continues for as long as 40 hours. During

this early period there may be a tremendous concentration of blood. Such fluid imbalance is primarily due to an altered capillary permeability with a shift of fluid and proteins into the tissues rather than an external loss of these substances. The need for water and electrolytes is moderate only since the excess fluid in the tissues should be available when plasma osmotic pressure is restored to a normal level. Administration of excessive amounts of normal saline without plasma protein only increases an edema already present and must be given in dangerously large amounts to have any significant effect upon the plasma volume. For the correction of this situation Elkinton and his associates recommended the frequent intravenous injections of plasma, in amounts varying according to the need, without the administration of excessive amounts of protein free fluids. Scudder (16) recommended the intravenous use of hypertonic saline solution in conjunction with adrenal cortical extract and showed that these agents have a great effect upon plasma volume in the absence of quantitative protein replacement. Throughout the study and treatment of patients with severe burns frequent plasma protein determinations in relation to hematocrit readings are of the utmost value in indicating the proper therapeutic measures.

In 1938 Scudder, Zwemer and Whipple (18) reported a large series of collected cases of acute intestinal obstruction with an analysis of the clinical and pathological data. Twenty-five patients who came under the direct observation of the authors were subjected to an intensive study. On the basis of these observations the authors drew definite conclusions regarding the efficacy of controlled fluid therapy. The next year Scudder, Drew and Sloan (17) reported in detail a case of acute appendicitis complicated by multiple abscesses in which it would appear the patient's life was preserved only because of the direction of treatment by a definite program of fluid control. They emphasized the observation that earlier than blood pressure changes increasing peripheral hemoconcentration foretells impending circulatory collapse and recommended the adoption of a program of careful fluid balance for all severely ill pa-

tients, stressing the efficacy of concentrated saline, adrenal cortical extract, and plasma as therapeutic agents in combatting impending shock. Scudder and his associates indicated that proper fluid control therapy in surgical conditions producing disturbances in physiological fluid balance can be directed after careful study and rational interpretation of information concerning cell volume and plasma protein levels.

EXPERIMENTAL STUDY

The material presented in this report includes data accumulated from a study of experimental *Staphylococcus septicemia* in dogs and data acquired in observations of patients admitted on the surgical services of Charity Hospital in New Orleans with diagnoses of *Staphylococcus septicemia*.

Observations were completed upon 15 dogs divided into two groups of 7 and 8 animals, respectively. Group I was composed of 4 adult dogs and 3 four month old puppies. Group II was composed of a litter of 8 two month old nursing puppies. Throughout the experiments they were given bountiful quantities of pabulum and standard dog foods. In addition, Group II puppies were allowed to nurse. Fluids were unrestricted, but no attempt was made to force feeding or to administer treatment.

During 2 weeks preceding the experiments normal values were established for hematocrit or red blood cell count and plasma proteins. Blood cultures were taken repeatedly before the beginning of the experiments and were found to be negative. The method used for plasma protein determination was the falling drop method of Barbour and Hamilton (1, 2, 3).

A strain of hemolytic *Staphylococcus aureus* recovered from a human case of *Staphylococcus septicemia* was cultured for 18 hours in dextrose beef heart broth. One cubic centimeter of this inoculum was injected into the right femur of each dog in Group I. Before use in Group II the organism was made more virulent by animal passage, and the 18 hour dextrose beef heart broth culture was concentrated by centrifugation until 1 cubic centimeter of the final inoculum contained 30×10^9 bacteria. One cubic centi-

meter of this preparation was injected into the right tibia of each animal in Group II.

Five dogs of Group I survived, but only 1 animal died as a result of the hemolytic *Staphylococcus aureus septicemia*. All the animals of Group II succumbed after intervals varying from 2 to 17 days. Determinations of hematocrit or red blood cell count, plasma proteins, and blood cultures, together with clinical observations, were made at regular intervals for 16 days or until the dogs died. Autopsies were performed on the 10 dogs which succumbed. Cultures were taken of the various parts, and sections were prepared for microscopy. Septicemia was produced in all of the animals, but the blood culture colony counts were much higher in the dogs of Group II. Limited osteomyelitis was present in 9 of the autopsied animals. Metastatic abscesses were found three times in the lungs, twice in the liver, and twice in the kidneys. Marked degenerative changes in the liver, kidneys, and heart were constant findings.

In this study of hydration the method employed by Scudder (9, 16, 17, 18) and his associates was used, since the simple determination of cell volume and plasma proteins gives much useful information concerning fluid balance.

It has been shown by Stebbins and Leake that there is a diurnal variation of as much as 0.044 in the specific gravity of dog blood. Barbour and Hamilton (3) ascribed changes of 0.040 in the specific gravity of dog blood to "emotional anhydremia." Variations are known to occur also in the cell volume and red blood cell counts of normal blood. Because of these normal daily variations in individual animals, composite graphs of the data at hand give more representative pictures of the changes in hydration, occurring in the respective groups of animals under the experimental conditions set forth, than do individual records. Accordingly, observations will be made and conclusions drawn largely on the basis of the composite graphs seen in Figures 1, 2, 3, 4.

Group I The hematocrit curve (Fig 1) rose perceptibly in relation to the hyperpyrexia which developed during the first 4 hours after inoculation. Thereafter, there was an uneven

Fig. 2. Group I animals hematocrit determinations. Average hematocrit curve of 7 dogs during mild *Staphylococcus septicaemia*. The final spectacular rise as caused by single specimen from animal.

but progressive fall in the average hematocrit level until a value of approximately 30 was reached and maintained for several days. The final spectacular rise in the curve was caused by a single specimen from 1 dog. The average plasma protein curve (Fig. 3) starting from a base line of 5.48 grams per cent made a considerable rise on the second day after inoculation and maintained itself irregularly at a level well above the base line. The final rise in the curve was formed here also by a single specimen.

By placing the hematocrit and plasma protein curves in relation to each other one is able to make a reasonable interpretation of the changes which occurred in this particular group of animals. The general picture resembles the idealized graph which Drew Scudler and Pappas (9) thought typical of "water loss with anemia." If it can be assumed that

Fig. 3. Group I animals plasma protein determinations. Average plasma protein curve of 7 dogs during mild *Staphylococcus septicaemia*.

the increased levels of plasma protein were caused by concentration of blood due to water loss the degree of the anemia was in reality greater than that represented.

Group II The average red blood cell curve (Fig. 4) beginning at a base line of 3,500,000 cells per cubic millimeter fell rapidly and consistently to a level of approximately 2,500,000 cells per cubic millimeter which was reached on the sixth day and was maintained thereafter except for a single specimen from the 1 surviving dehydrated dog on the seventeenth day. The average plasma protein curve (Fig. 4) which rose perceptibly on the second day as did also the curve for Group I was maintained above the base line only until the fourth day. Thereafter there was a sharp decline of the curve to a level below 4 grams per cent. The exceedingly low value of 3.16 grams per cent was reached by a single specimen from the 1 dog surviving on the seventeenth day.

Fig. 4. Group II animals red blood cell curve of 8 dogs during mild *Staphylococcus septicaemia*. The final single count from animal shortly

Fig 5 Clinical Staphylococcus septicemia hematocrit determinations Composite graphs of hematocrit determinations during Staphylococcus septicemia in two groups of patients

Fig 6 Clinical Staphylococcus septicemia plasma protein determinations Composite graphs of plasma protein determinations during Staphylococcus septicemia in two groups of patients

Again placing the red blood cell curve and the plasma protein curve in relation to each other, one is enabled to make a reasonable interpretation of the variations in fluid balance which occurred. During the first 4 days following inoculation, when there was a steady fall in the hematocrit curve but a moderate increase in plasma protein values, the relation resembled the idealized "water loss with anemia" picture seen in Group I. Between the fourth and fifth days the relation of the respective curves changed to one indicating both red blood cell and plasma protein depletion. If clinical judgment to the effect that the animals were in states of comparative dehydration is correct, the true values for red blood cells and plasma proteins were even lower than those indicated by the curves.

Reasons for the marked decline in the hematocrit curve and the red blood cell curve in the respective groups of animals remain matters for speculation. The actual blood loss incident to the frequent taking of specimens was not great. Since less than 20 cubic centimeters of blood was withdrawn from any animal of Group II in the 25 days during which the observations were made, it does not seem probable that blood so lost figured largely in the more than 28 per cent decline in the red blood cell level. The possibility that there was a depression of the hemopoietic function of the bone marrow is not borne out by the marked erythroid and myeloid activity seen in sections of the bone marrow. Malnutrition may have been a factor, although in each group the greatest decline in the curves

occurred by the sixth day after inoculation, which is a relatively short period for changes from malnutrition to become evident. Staphylococcus hemolysins are capable of rapid destruction of blood, however, microscopy did not reveal any unusual amount of pigment in the reticuloendothelial system, nor was jaundice seen clinically. Loss of hemorrhagic exudates into the intestine and lungs and by external discharges may have been a causative factor in the anemia of 2 of the dogs.

It is easier to suggest reasons for the variance of the plasma protein curves of the two groups, inasmuch as differences in the respective clinical courses were marked. The matter of exudates supplies a ready explanation. Whereas 5 of the animals of Group II produced copious exudates, only 1 dog in Group I lost any considerable amount. However, 2 dogs, which had no marked exudative loss, had lower protein levels than the other animals in Group II.

Destruction of plasma proteins by the direct action of a staphylococcus toxin must remain a hypothetical possibility. Indirect action of such toxins in causing degenerative changes in the liver offers a more likely explanation, if it can be assumed that the advanced state of cloudy swelling and fatty degeneration, observed in all of the histological

Fig. 1. Group I animals hematocrit determinations. A large hematocrit curve of 7 dogs during mild *Staphylococcus septicaemia*. The final spectacular rise as caused by single specimen from animal.

but progressive fall in the average hematocrit level until a value of approximately 30 was reached and maintained for several days. The final spectacular rise in the curve was caused by a single specimen from 1 dog. The average plasma protein curve (Fig. 2) starting from a base line of 5.48 grams per cent, made a considerable rise on the second day after inoculation and maintained itself irregularly at a level well above the base line. The final rise in the curve was formed here also by a single specimen.

By placing the hematocrit and plasma protein curves in relation to each other one is able to make a reasonable interpretation of the changes which occurred in this particular group of animals. The general picture resembles the 'idealized graph which Drew Scudder and Pappas (9) thought typical of 'water loss with anemia.' If it can be assumed that

Fig. 2. Group I animals plasma protein determinations. Average plasma protein curve of 7 dogs during mild *Staphylococcus septicaemia*.

the increased levels of plasma protein were caused by concentration of blood due to water loss, the degree of the anemia was in reality greater than that represented.

Group II The average red blood cell curve (Fig. 3) beginning at a base line of 3,500,000 cells per cubic millimeter fell rapidly and consistently to a level of approximately 2,500,000 cells per cubic millimeter which was reached on the sixth day and was maintained thereafter except for a single specimen from the 1 surviving dehydrated dog on the seventeenth day. The average plasma protein curve (Fig. 4) which rose perceptibly on the second day as did also the curve for Group I was maintained above the base line only until the fourth day. Thereafter there was a sharp decline of the curve to a level below 4 grams per cent. The exceedingly low value of 3.16 grams per cent was reached by a single specimen from the 1 dog surviving on the seventeenth day.

sections of liver was due, in part, to bacterial toxins. Since the liver is thought to assume an important rôle in the production of proteins the level of the plasma proteins may be an important indicator of liver health. The relation between hypoproteinemia and liver damage in hyperthyroidism and obstructive jaundice has already been mentioned (14). Attention has been directed also, to hepatic changes reported after experimental dehydration (8). Animals in Group II became more dehydrated than those of Group I, and it is probable in view of the procedure used and the clinical course followed by each group that dogs of Group II were exposed, also, to bacterial toxins of greater potency and in greater amounts. It is reasonable to suppose that the degenerative changes observed in sections of liver removed at autopsy were greater than those in the animals which survived and that a lower plasma protein level occurred in Group II partly as a result of more extensive liver degeneration.

Failure to find edema in the face of extremely low plasma protein levels is one of the interesting observations of the study. In 5 animals of Group II plasma protein determinations of less than 3.7 grams per cent were recorded. Jones and Eaton (11) in reporting repeated estimations of less than 3.6 grams per cent in a patient, never subject to edema, suggested that the explanation lay in the ex-

aggerated state of dehydration of their patient. Curphey and Orr and Keefer stated that edema rarely occurs, even in the presence of very low plasma protein, without the administration of the sodium ion, usually as sodium chloride. Explanation of the absence of edema in these experimental animals may be found, therefore in their dehydration and their failure to receive any considerable amount of sodium chloride.

CLINICAL STUDY

Sixteen Charity Hospital patients, each having a clinical diagnosis of *Staphylococcus septicemia*, were observed, and of these 8 were chosen for this report. Repeated blood cultures drawn from each of the 8 patients were positive for the hemolytic *Staphylococcus aureus*. Controlled fluid therapy was employed in each instance, but varied in detail according to the training and diligence of the respective internes and residents. Frequent hematocrit and plasma protein determinations were made in order to furnish data for comparison with those obtained in the study of the experimental animals. Four of the patients survived, whereas the remainder succumbed. In order to correlate the findings in this study with those obtained in the experimental investigation already described, the 8

Fig 10 Graphs of hematocrit and plasma protein determinations during Staphylococcus septicemia in a girl of 14 who died in spite of comparatively large amounts of blood by transfusion (3900 cubic centimeters between the fourth and eleventh days). This patient was one who became markedly edematous before death

patients were divided into groups according to survival. Composite graphs of each group's hematocrit and plasma protein readings were made.

Figure 5 shows the composite graph of the hematocrit determinations in each group of patients. It fails to demonstrate the consistent lowering of the hematocrit level which was so striking in both Group I and Group II animals of the experimental study. It would appear that the numerous transfusions which these patients received were sufficient to maintain or raise to comparatively normal levels the hematocrit in those patients who succumbed as well as in those who recovered. Figure 6 shows the composite graph of the plasma protein determinations in each group of patients. Here a striking difference is observed in the response of the two groups. Each curve fell sharply immediately after admission of the patients to the hospital as adequate hydration was obtained by the employment of parenteral fluids. In the course of treatment, however, the plasma protein curve of those patients who survived rose rapidly to normal and even unusually high levels, whereas, the composite curve of those patients who succumbed failed to show this response. These later observations correspond to those in the experimental study in which it was observed that the plasma protein curve of the Group I dogs

which survived maintained a better than average height, whereas, the curve of the Group II dogs which succumbed fell consistently.

Corroboration of the impressions conveyed by the composite graphs may be had by an examination of Figures 7, 8, 9, and 10, which show the hematocrit and plasma protein curves of each of 4 patients. Graphs of patients who survived are shown in Figures 7 and 8. Comparatively large amounts of citrated blood were given to each child, and the plasma protein response was striking. Graphs of patients who succumbed are found in Figures 9 and 10. In each instance the hematocrit curves were maintained at a high level by the frequent transfusions, but there was no like response on the part of the plasma protein which remained at subnormal levels until the death of each patient. The patient whose graphs are shown in Figure 9 was an adult male, who, undoubtedly, received transfusions of blood too infrequently and in too small quantity. It is a matter of speculation whether or not larger and more frequent transfusions might have raised the plasma protein level to normal, thus influencing favorably the ultimate outcome. The patient represented by Figure 10 died in spite of comparatively large

and frequent transfusions and her plasma protein level though rising had never reached a normal point. It is interesting to note that 2 of the patients became quite edematous before death in each instance this followed the judicious use of sodium chloride administered intravenously.

CONCLUSIONS

Although the number of experimental animals and of patients observed during this study is comparatively small the data accumulated have been so consistent in certain respects that they were deemed worthy of report, particularly since there seems to be a justifiable practical application.

In experimental *Staphylococcus septicemia* in dogs there was a marked fall in the hematocrit level both in animals fatally ill and in those ultimately recovering. Patients afflicted with *Staphylococcus septicemia*, whether they survived or died were able to maintain normal hematocrit ranges with the aid of numerous transfusions.

In untreated experimental animals and in patients undergoing intensive therapy a distinct line is drawn by plasma protein levels between those (animals and patients) who survived and those who succumbed. The plasma protein curves of the former maintained or reached a better than average level whereas the curves of those who succumbed steadily fell or failed to rise even in the instance of the patients who received intensive treatment including numerous blood transfusions.

It is our belief that these observations are a sufficient basis for considering the plasma protein levels observed clinically in *Staphylococcus septicemia* as a valuable prognostic aid. It would appear that the plasma protein level

falls in all patients having *Staphylococcus septicemia*, but that in those instances in which recovery is to occur the proteins rise and are maintained at a high point after adequate therapy. Since it has been shown that the plasma protein responds more slowly to repeated transfusions than does the hematocrit, the former should be used as a therapeutic guide to indicate the need for blood transfusions. Large amounts of whole blood or plasma, repeatedly administered, give the greatest opportunity for recovery.

CHEMOTHERAPY AND ROENTGEN RADIATION IN CLOSTRIDIUM WELCHII INFECTIONS

Clinical and Experimental Studies

ROBERT L SEWELL, A B, M D, ANDREW H DOWDY, A B, M D, and
JAMES G VINCENT, A B, Rochester, New York

CLINICAL clostridium infections range in severity from relatively benign infections to more fulminating and malignant types. The etiological organism may be either *Clostridium welchii*, *Clostridium septicum*, or *Clostridium oedematiens*, or a combination of the three. Our present clinical and experimental studies are confined to *Clostridium welchii*, for this is by far the most common offender clinically.

There is doubt in the minds of many as to just what "gas gangrene" really is. The present controversy over the proper therapeutic measures leaves no doubt that many criteria may be loosely interpreted. The term "gas cellulitis" or "clostridium cellulitis" is suggested not to supplant the term "gas gangrene," but to provide a hitherto missing category in which to place the milder, the borderline, and the atypical case.

We have come to give less credence to the term "gas gangrene." Does such an entity really exist, or does it simply include the more fulminant cases of clostridium cellulitis? "Cellulitis," either used or implied, is a more inclusive term and is perhaps more apt in emphasizing the bacterial origin and nature of the infection. There are cases that have become fulminating within several hours, and there are other cases which have developed slowly. The infection may extend largely in both the subcutaneous tissue and muscle in another, even though both patients are equally sick. There have been a few cases of superficial *Clostridium welchii* infection with persistently positive cultures, at times with small amounts of gas in the immediate vicinity but with an essentially benign course. These latter cases have been excluded from the present series even though we believe that they are milder manifestations of the same infection.

It is possible that the disease which we are accustomed to see differs in some way from the classical description. Definite muscle involvement is usually not proved now that more conservative measures are used. In our study, therefore, the criteria for calling cases "gas gangrene" are (1) positive cultures of *Clostridium welchii*, (2) spreading infection, (3) gas in the tissues, and (4) discoloration and edema of the involved structures (17).

One of our first concerns has been to establish the presence of a true "gas gangrene." Regardless of whether or not this is done, any spreading infection with *Clostridium welchii* found in the culture, or any infection with gas in the tissues has been treated as a severe case. If the four criteria were not all met, the case was not included in our series. Among those omitted were 4 simple *Clostridium welchii* infections, 2 of which presented small amounts of gas in the tissues (Table I). In 2 additional cases, crepitus was noted but no *Clostridium welchii* were found. The offenders were *Escherichia coli* in one case, and in the other an anaerobic streptococcus and a hemolytic staphylococcus.

CLINICAL EVALUATION OF PRESENT THERAPEUTIC AGENTS

Sulfanilamide, sulfapyridine, sulfathiazole,
roentgen irradiation, antisera, zinc peroxide

TABLE I—CLINICAL WOUND INFECTION WITH CLOSTRIDIUM WELCHII

J. W.	25 yrs.	Mangled fingers	Irradiation	Well
W.	3	Infected heel	Irradiation	Well
R.	58 yrs.	Cervical abscess of lower back abscess	Sulfanilamide, irradiation	Dead (wound closed)

pastes, and the inhalation of high concentrations of oxygen have each been recommended recently for the treatment of *Clostridium welchii* infections. The multiplicity of these agents and the disparagement which each in turn has received implies that a method of appreciable superiority is still wanting. On the other hand, the mere fact that no one is advocating a continuation of the previously prevalent radical surgery suggests that the various sulfonamide drugs roentgen irradiation or the antiserum may each favorably modify the course of the disease. We believe that the diversity of opinion regarding the relative merits of any one of these therapeutic agents may in part be due to the wide variation in the severity of this type of clinical infection that is a true "gas gangrene" as here defined or a *clostridium* cellulitis.

Antiserum. The polyvalent antiserum, in efficient at best when used alone, can easily be proved to be of some value experimentally (10-13). In mice and guinea pigs it is more efficacious than is sulfanilamide. In clinical use the polyvalent antiserum gives acceptable results when used with conservative surgery, but prophylactically its effect is feeble (1-14). That this should be so follows rationally when one compares the antiserum for *clostridium* infections with the antiserum for tetanus. In the latter disease the antiserum combats, and very effectively the tetanus exotoxin which has a systemic effect while the action against the usually insignificant local lesion is minimal. The local source of infection is usually small and tends to heal itself.

In the case of *Clostridium welchii* infections, the antiserum may well control the exotoxins distributed throughout the body but these are of far less magnitude than is the virulent local lesion which progresses rapidly killing

more tissue and forming exotoxins far in excess of the amount that the polyvalent antiserum can control.

In prophylactic use the same situation holds. The tetanus antiserum neutralizes the exotoxins as they are liberated from the small local wound. In *Clostridium welchii* infections, the local lesion tends to spread often rapidly regardless of the systemic effect of the exotoxin. Therefore, the *welchii* antiserum could act through its effect on the local lesion immediately adjacent to the wound. At best it could only slow down the advancing necrosis.

For these reasons we do not insist on the use of *Clostridium welchii* antiserum either prophylactically or therapeutically. We have used it but twice in our last 18 cases. It is important to note however that the protective action of the antiserum in small animal experiments is far greater than it is in humans.

Surgery. In contrast to the past, the need for amputation now is dictated not as much by the infection as it is by the state of the vascular bed. The coexistence of vascular damage to an extremity plus a *Clostridium welchii* infection has often distorted the picture. The infection was held mainly to be responsible for not only the gas, edema, and seropurulent exudate, but also for the massive necrosis, discoloration and particularly malignant course. While the radical measure of amputation is still accepted in this extreme there is no question but that a wound infection with only *Clostridium welchii* or with other contaminants too may run an exceedingly indolent course. When in the muscle (deeper wounds) the progression is more rapid and more serious and there is evidently a distinct local necrotizing effect of the toxin. However this is shared by other organisms and is seen not infrequently. Perhaps the most common of the others is the cellulitis caused by the streptococcus. The opportunity for growth of *Clostridium welchii* not shared by the other organisms is the remarkable ability to form gas. This may facilitate the dissection along fascial planes and cause a certain amount of pressure to be exerted.

The contrast between the classical picture of a gas gangrene and many of the wounds

seen in civil life suggests that there are many of these infections which might be called "clostridium cellulitis" or "gas cellulitis". Many of the latter are quite fulminant, and easily fulfill the criteria of a "gas gangrene". However, the presence of a relatively intact vascular bed leads to conservative measures

In arteriosclerotic gangrene and in similar infections, amputation is going to be necessary in a number of cases regardless of whether a Clostridium welchii infection is present or not. Therefore, it is too much to presume that any measure will cure the infection at a site where the part is unable to survive even without the infection. The appearance of the disease in a stump following amputation may well be treated conservatively by simple drainage measures plus one of the sulfonamides or roentgen irradiation, rather than by higher amputation. This is assuming that a relatively intact vascular bed is present in the stump.

In the traumatic cases in which there is considerable destruction and mangling of the tissues (and again assuming that there is no great arterial damage), the infections may safely be treated conservatively. With adequate drainage (we do not use débridement although many advocate it) and the use of roentgen irradiation or a sulfonamide, we believe that we have obtained good results.

Roentgen irradiation. In this series we have included every patient who has been in the

Strong Memorial Hospital with "gas gangrene" since 1937 (Tables II and III).

Roentgen irradiation has a definite beneficial effect on the course of the disease. During the last 4 years we have seen fit to use this agent in all but 1 of our cases. In several instances the response to irradiation has been clearcut since no other therapeutic measures were being taken at the time (17).

On the other hand, our results with roentgen irradiation have not been as good as have those of Kelly (11). There have been 5 deaths in our series of 15 cases of "gas gangrene". One of these (C T, Table III) was a frank therapeutic failure. Another death occurred 30 days after the infection had been controlled and treatment had been stopped. Since death was caused by an advanced carcinoma of the testicle, perhaps this case should not be included as a failure.

The remaining 3 deaths occurred with considerable similarity in patients 68, 70, and 85 years old in whom the general physical condition was poor (Table II). The Clostridium welchii infection did not seem to have any more bearing on their demise than did co-existent pneumonia and advanced arteriosclerosis. Two of these 3 patients had recently suffered amputations because of arteriosclerotic vascular disease of the legs. On the other hand, there have been several reports of distinctly unfavorable outcomes (6, 7). Caldwell's studies of the effect of irradiation on guinea pigs led him to believe that irradiation

Fig. 1. Photograph of control dog 30 days after inoculation.

Fig. 2. Photograph of dog treated with sulfadiazine 10 days after inoculation.

was of extremely little value (5). More recently a series of studies of compound fractures contaminated by *Clostridium welchii* were reported (4). In that series, all of his control animals died while 30 per cent of the treated animals survived.

Sulfonamides plus roentgen irradiation. Is the use of both irradiation and a sulfonamide advisable. Until recently there has been no clinical or experimental proof that these two should not be used together. It has been suggested that the combined use is contra-indicated (11, 12). Until the last few months we had assumed perhaps unjustifiably that the measures were probably complementary. The majority of our patients were given either roentgen irradiation plus sulfanilamide or roentgen irradiation plus sulfadiazine with success. As we see only 3 or 4 clinical cases of *Clostridium welchii* infection a year it is impossible to present a series of any significant size. However if we assume that our method of approach in dogs is reasonably comparable roentgen irradiation plus sulfadiazine gives poorer results than does either one alone (Table IV).

Sulfonamides. Although the use of the sulfonamide drugs is in favor only a few small series have appeared (2, 17). These have been treated mainly with sulfanilamide. Our experience is not conclusive since most of our patients have been treated predominantly by irradiation, and more recently by sulfadiazine.

Sulfanilamide was used in 10 earlier cases because we believed that it might prove to be an adjunct to roentgen irradiation. In the few instances in which the patient was maintained on the drug alone for a reasonable period before irradiation was started the infection was not brought under control.

These scattered clinical impressions are borne out fairly accurately by the experimental results. Four observers (3, 4, 9, 10) have found that in guinea pigs there is a distinct protective action and some curative effect by the drug. Others disagree but admit that sulfathiazole has some effect (15). Sulfathiazole is more efficacious than either sulfanilamide or sulfapyridine (10, 15) and again the best experimental results were obtained by local use. No reported series is yet available but Wilson mentions that sulfathiazole plus antiserum and conservative surgery are being used predominantly on these infections in England at present. One patient that we treated with both sulfathiazole and roentgen irradiation made a satisfactory recovery.

We have given sulfadiazine to 3 patients with *Clostridium welchii* infections in addition to applying it to the local lesion. In each case the infection was brought under control rapidly and within 2 to 3 days clean granulations covered a good portion of the affected area. One of these patients received nothing at any time but sulfadiazine while in the other 2 this was supplemented by roentgen

irradiation One of the latter died from other causes

EXPERIMENTAL CLOSTRIDIUM WELCHII INFECTION IN DOGS

Roentgen irradiation in clostridium welchii infections was used for about 6 years before there was any experimental confirmation of its action. In large part this was due not to a lack of effort, but to a lack of adequate proof. Our first year of laboratory investigation was conducted on guinea pigs. We were not able to produce a satisfactory facsimile of a human "gas gangrene" because the spread through the tissues was so rapid that it became a generalized disease rather than a local one so that local roentgen irradiation was not effective. The irradiated group did a little better than the controls but the results were not statistically significant.

For an experimental test of the effects of roentgen irradiation and chemotherapy, we have produced *Clostridium welchii* infection experimentally in 255 dogs. This results in an infection which is quite similar to the disease in humans and is one which progresses somewhat more slowly through the tissues than it does in smaller animals (8). The disease was produced by injecting 1 to 1.5 cubic centimeters of a 20 hour, deep meat, subculture of a single strain deep into the thigh muscles. This strain was from a fatal case of *Clostridium welchii* infection and had remained undisturbed in an icebox for 6 months. By taking the subculture each week from this master culture we were able to minimize the changes in toxicity and virulence that one working with these preparations must contend with.

Usually within 3 hours after injection, there was edema and tenderness of the thigh with gas palpable deep in the tissues. When undisturbed, the infection progressed rapidly. It dissected into the lower thigh and up into the abdominal wall usually with a fatal result in 24 hours.

Roentgen irradiation Of the 89 animals in the irradiation group, 50 received roentgen irradiation after the infection had become established (therapeutic irradiation), and 39 were kept for controls. The experiment was

TABLE IV — COMPARISON OF SULFADIAZINE, IRRADIATION, AND COMBINATION OF TWO USED THERAPEUTICALLY IN DOGS WITH CLOSTRIDIUM WELCHII INFECTION

	No	Survivals	Per cent
Roentgen irradiation			
Controls	50	13	26
Sulfadiazine	39	7	17.9
Controls	25	7	28
Sulfadiazine plus roentgen irradiation	15	1	6.7
Controls	25	3	12
	12	3	25

carried out in groups of 4 to 10 dogs injected simultaneously. Of the irradiated animals, 26 per cent survived (Table IV), and of the control group, 17.9 per cent survived. From the experimental standpoint, roentgen irradiation would not seem to be logical as a prophylactic measure.¹

Sulfadiazine and roentgen irradiation When sulfadiazine combined with roentgen irradiation was given after the infection was well established in 25 dogs, there was a survival of only 12 per cent (Table IV). We have no explanation for this apparently antagonistic effect between roentgen irradiation and sulfadiazine. Work in progress may clear up this paradox. For the present we offer it only as preliminary evidence that the two methods are not complementary and should not be used in conjunction with each other.

Sulfonamides Our experience with sulfanilamide in dogs is comparable to that of other workers in this field. When used *prophylactically* (if the concentration of the drug in the blood is raised to therapeutic levels prior to the inoculation with the infectious agent), sulfanilamide gave a survival of 60 per cent in 15 dogs. Under the same conditions, butyryl sulfanilamide (a highly soluble preparation of sulfanilamide) gave 30 per cent survival out of a group of 10 dogs, while of 37 dogs in the control group, there was only a 16 per cent survival (Table V). When sulfanilamide is used *after* the infection is established, the advantage over the control group should be considerably less as judged by our results with

¹The same group of controls has frequently been used for one or more experiments run concurrently.

TABLE V.—CLOSTRIDIUM WELCHII INFECTION IN DOGS TREATED PROPHYLACTICALLY

	No.	Survivals	Per cent
Controls	37	6	16
Butyryl sulfadiazine	20	3	30
Sulfadiazine	5		60
Sulfadiazine	25	10	28

	Dogs	Survivals	Per cent
Sulfadiazine	15		28
Control	5		7

sulfadiazine. Other variations of the technique suggest that the drug used locally is a little more efficacious than when given parenterally. In view of the results obtained with sulfadiazine the prophylactic value of these two drugs was not sufficient to warrant a therapeutic test on dogs.

These results are fairly consistent with the reports of others for *Clostridium welchii* infection but with *Clostridium septique* and *Clostridium oedematis* there is considerable contradiction (9, 10, 16).

Sulfadiazine. Sulfadiazine has been superior in our hands to other drugs. When used prophylactically in 25 dogs with experimental *Clostridium welchii* infection, there was an 88 per cent survival. The control group of 37 dogs (the same used in the preceding group) presented a 16 per cent survival. As shown in Table V this is appreciably better than any results we had obtained with sulfanilamide preparations. After the infection was established in 25 dogs, the sulfadiazine was given therapeutically (3 hours after inoculation) and there was still a 28 per cent survival. This is in contrast to a survival of 6.7 per cent of 15 control dogs run concurrently (Table VI). None of the procedures used has actually aborted the infection.

In the prophylactic experiments with sulfadiazine many of the animals showed none of the toxic symptoms which we were accustomed to see. The dogs would often feel well enough to walk about instead of lying prone

in their cages. The accompanying photographs (Figs. 1 and 2) show the difference between a control and one of the sulfadiazine treated dogs at the end of 10 days.

CONCLUSIONS

From our experience it seems that a number of cases of *Clostridium welchii* infection fall awkwardly into the group called "gas gangrene." For this group the term "clostridium infection" seems rather inadequate but "clostridium cellulitis" is a reasonably descriptive term. There is undoubtedly a wide variation in the manifestations of the disease.

The complementary use of conservative surgery with either a sulfonamide or roentgen irradiation gives as good results as we know how to obtain at present. The reservation of amputation for these cases in which there is a markedly compromised vascular bed is warranted.

Both sulfanilamide and roentgen irradiation when employed alone have some beneficial effect on the course of the infection both experimentally and clinically, and lately we have used sulfadiazine in 3 patients with success. All of these observations are borne out more or less clearly by animal experimentation. The results have been especially encouraging with sulfadiazine. The prophylactic use of the sulfonamides is invariably superior to administration of the drug after the infection is under way.

The development of the experimental aspects of the studies has been delayed by the variance of strains, loss of virulence and by the multiplicity of therapeutic measures used. All of these variables must be considered in grading experimental results.

We believe that it is essential particularly in the study of this infection to reproduce a disease which resembles closely that seen in humans. In our hands this ideal has been more nearly fulfilled in dogs than with any of the other laboratory animals. The resemblance is closer to the human reaction in all respects. As seen from the charts, there are always a few of the controls that survive (6.7 to 25 per cent) but there has always been a

Of nonoperative control dogs, the average survival has been 14 per cent.

Anyone familiar with the use of sulfathiazole is aware of the various manifestations of drug intoxication. These include fever, rash, and conjunctivitis chiefly, nausea and blood destruction do not occur so frequently. All of these phenomena were observed in the present series, and on a few occasions it was necessary to discontinue the drug, but this happened in only 1 of the 5 fatal cases.

Table II offers an interesting comparison. Despite the smaller size of the second group certain remarks may be made. I believe that the low incidence of deaths from generalized peritonitis is due to the effect of sulfathiazole, and in the cases of the 2 patients who succumbed the postoperative course was prolonged far beyond the most optimistic expectations.

The absence of deaths resulting from unrecognized mechanical ileus or from unrecognized subphrenic abscess is not due to the lack of these complications, for they occurred with their usual frequency, nor can the fact be ascribed solely to the use of sulfathiazole. It is in this group of patients, with complications treated inadequately in the earlier series, that better methods of postoperative care have brought about improved results.

The single patient considered to be inadequately treated was a 7 year old boy who had generalized peritonitis of appendical origin. He improved steadily for 8 days after opera-

tion, and then a definite pelvic abscess formed. This was recognized, but palliative therapy was attempted rather than surgical drainage. On the thirteenth day after operation the abscess suddenly ruptured, and the patient died in a few hours.

That no deaths occurred from pneumonia is probably the result of the chemotherapy.

The single fatality placed in the "poor risk" category was that of a male of 58 years who entered the hospital with generalized peritonitis and in acidotic coma. He was found to have diabetes mellitus, and the blood contained 460 milligrams per cent of sugar. Efforts to regulate the diabetes and to improve his condition generally were unavailing. He died 2 days after operation.

In summary, it can be fairly stated that sulfathiazole given by vein or by mouth is a useful adjunct to the treatment of perforative appendicitis. An equally potent factor in the improved results obtained in the Johns Hopkins Hospital during the past 2 years has been the more adequate treatment of postoperative complications. Although this series of cases is small, the trend is in the right direction and serves to strengthen my conviction that immediate operation is the correct treatment for acute appendicitis in any stage of the disease.

THE VALUE OF SULFATHIAZOLE IN THE TREATMENT OF PERITONITIS AND ABSCESES OF APPENDICAL ORIGIN

EDWARD S. STAFFORD M.D. F.A.C.S. Baltimore, Maryland

IN a previously reported series (1) of 479 consecutive cases of peritonitis or abscess of appendical origin in all of which the condition was treated at the Johns Hopkins Hospital by immediate operation, there were 48 deaths, a mortality rate of 10 per cent. This mortality rate compares favorably with those reported from other hospitals of similar size and is somewhat lower than the average of results reported for the delayed or expectant treatment of perforative appendicitis. A study of the fatal cases, however, showed that at least 14 of the deaths were the result of inadequate diagnosis and treatment of complications which arose days or weeks after the initial operation.

Since then 2 years have elapsed, during which period a second group of consecutive cases has been treated. This series although numerically smaller resembles the earlier one exactly as regards type of patients, proportion of appendical perforations on admission and incidence of the various postoperative complications, but less than half of the expected number of deaths occurred. The treatment of the patients in this second group differed from that of the earlier series by the use of sulfathiazole in nearly all instances, and by more careful observation and treatment of those patients who did not recover promptly after operation. As in the earlier series, every patient was subjected to immediate operation. From September 1, 1939, to September 1, 1941 there were 105 patients who had peritonitis or abscess of appendical origin and only 5 of them died. Postmortem examination was made in 4 of these.

Others have reported on the use of sulfanilamide and related drugs in the treatment of perforative appendicitis, and in most instances the drugs have been used locally in the wound,

or in the peritoneal cavity. In the present series of cases sulfathiazole was administered intravenously and/or by mouth, none being used locally. It was desirable to give this method a thorough trial so that an evaluation could be made and it seemed that spreading infections and infections of extra appendical origin, such as pneumonia, might be more effectively dealt with in this manner. An initial dose of 4 grams of sulfathiazole was given to the average adult, and this was followed at regular intervals by a sufficient amount of the drug to maintain a level in the blood of 6 to 8 milligrams per cent. The first dose or two was usually administered intravenously and thereafter the drug was given by mouth unless it was found that the patient was unable to retain it.

Presented at the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

The contribution made by Winnett Orr when he pointed out the importance of wide open drainage, complete immobilization, and infrequent dressings cannot be overestimated. These wounds do not need to be dressed for 2 or 3 weeks and by that time are completely lined with healthy granulations and are well on the way to closure.

When the importance of this principle was thoroughly understood, a great change came into the treatment of the septic nonunions. Instead of limiting treatment to the infection and the osteomyelitis and waiting a year or two before attempting a bone graft operation, it became the general practice to deal with the nonunion at once by removing the sequestra, placing the freshened fragments in contact and immobilizing. The result in almost all cases was a quick union of the fracture and the saving of a year or two of hospitalization.

NERVE LESIONS

Of all the problems that the war brought to the reconstruction hospitals the most interesting was that of the lesions of the nerves. These cases were collected in special hospitals because in them the surgical staff was composed of men specially trained in extremity surgery and particularly qualified to deal with the deformities and disabilities that result from nerve lesions.

The rise of the neurological surgeon may lead to some agitation for a transfer of the nerve lesions from the orthopedic to the neurological surgeon, but from my observation of the two types of surgeon in action and from my own experience with both types of surgery, I would say that these patients are more likely to profit in the long run from the care of the modern orthopedic surgeon than from any other.

The lessons we learned about the wounds of the nerves were of the utmost importance and should be reviewed now if our young surgeons are to avoid our mistakes. Let me say that of all the remarkable things the surgeon does none is so spectacular in its results as the suture of a nerve. On the other hand no operation requires more attention to the details of technique if the best results are to be obtained.

Both in military and in civilian practice the question often arises as to whether a suture of a severed nerve should or should not be performed at the preliminary débridement. My answer is that if speed is necessary because of shock or hemorrhage or if there is the slightest risk of infection it should not be done. In clean incised wounds in which a thorough clean-up can be carried out it is justifiable, but in a shell wound, never. The business of the surgeon is to do a débridement as quickly and thoroughly as possible and to get the patient into an efficient splint and back to bed or on his way down the lines. The most that should ever be done to a severed nerve is to link the two ends with a catgut suture so that when the ultimate dissection is done the ends will be found close together.

The technique of nerve suture is well known, but I cannot refrain from referring to the absolute necessity of getting end-to-end contact if recovery is to be expected. To accomplish this all sorts of tricks must be resorted to, such as transferring the ulnar in front of the internal epicondyle and flexing the elbow acutely, flexing the knee to a right angle while repairing a 6 inch gap in the sciatic nerve and then placing the patient on his back with his hip in full extension and his leg dropped through a hole in the mattress so as to relieve tension on the sutures. In all these operations in which joints must be held flexed after the suture, a plaster bandage must be applied and left undisturbed for at least a month, that is, until the down-growing axis cylinders are well past the line of suture. After that a series of plasters must be applied at weekly intervals, and the joint straightened out gradually.

Occasionally the surgeon is confronted with a lesion in which the gap is so great that there is no hope whatever of bringing the severed ends into contact. If this happens in the musculospiral nerve it is of no great consequence because one can count on an extraordinarily good result from a transfer of flexor muscles into the extensors. But when it occurs in the median nerve it is a major calamity. Here there are three alternatives. First, one may dissect the nerve a long way back and then draw the two bulbs as closely together as they

SOME LESSONS LEARNED IN THE GREAT WAR

W F CALLIF M.D. F.A.C.S., Toronto, Ontario

TO those of us whose fortune it has been to serve our troops in time of war the spectacle of what is happening in Europe today cannot fail to make vivid again the memories of what we learned and to stir within us anew a burning desire to help our heroic men. If we are to be truly helpful however we must make sure that we have really remembered the lessons we learned and that we are prepared to apply to present war conditions all the lessons that are new.

In approaching this important subject one is apt to succumb to the temptation to comment on every field of surgery with which one has had any contact whatever. Thus it is with difficulty that I refrain from referring to the remarkable things that we saw and did in the gunshot wounds of the chest, abdomen and skull. On this occasion however I shall confine myself strictly to that field in which I have had a really broad experience and in which I should be able to speak with some authority.

Thinking over the compound fractures of the bones of the extremities, I would say that the greatest advance came from the introduction on the battle field or at the ambulance dressing station of adequate splinting. Everybody knows the spectacular reduction of the mortality rate that came with the introduction of the Thomas splint. Similarly there came a great improvement in the final results when the new methods of applying traction, such as by ice tongs, Sinclair's skates, and other devices were introduced. I have no doubt that further improvement will result from the Kirschner wire.

The outstanding impression left on my mind however from observation of large numbers of these patients at the convalescent stage was the very great difference in the quality of the results obtained in different hospitals. The explanation was perfectly sim-

ple for in one there was a leading spirit like Sinclair or Pearson or Blake whereas in another there was nobody interested in fractures. Surgeons had better get over the idea that anybody can treat fractures well enough, for the results that come from incompetent management are appalling. The remedy of course, is to see that at least one expert in fractures is attached to each surgical unit.

The most important contribution to the treatment of wounds in the last war was the preliminary débridement followed by the Carrel Dakin method of Irrigation. Whether the latter will be superseded by the new methods remains to be seen. With regard to these, however it would seem that if the bombing would allow a controlled experimental study of the new methods such as the Trueta or clusive treatment and the local and general use of the sulfonamide drugs, some definite conclusion should be arrived at before long. As things stand at present there is very little reason for confidence in the statements that are being made either for or against their use.

While practically all the compound fractures resulting from gunshot became infected, osteomyelitis was not a serious complication nor did it interfere greatly with the final result. Union went on in the usual way and of ten with greater osteogenic activity in the fragments than in simple fractures. Before my war experience it had always been my impression that infection was an important cause of nonunion. As an actual fact, however of a thousand infected compound fractures that passed through my hands, less than 50 failed to unite and when one came to investigate these one found that the nonunion in most cases was due to loss of bone.

The most important lesson learned in regard to chronic osteomyelitis and septic nonunion was that the patients could be operated upon without any serious risk of stirring up the infection and that if the wound was left wide open with gauze drainage extending into its depths they rarely had a rise of temperature.

is well fitted on the ends of the sectioned bones, and if the nerves are cut well back, it will stand up to hard usage for a lifetime

One of the chief causes of the unpopularity of the Syme operation has been the unfriendliness towards it of the artificial limb makers. Not many of them can make a good Syme artificial limb and even when they can they dislike it because it cannot be made symmetrical with the opposite limb. The result has been that whenever a Syme stump is the least bit defective, off it comes to make way for the pretty below-knee artificial limb. Unfortunately many a man has lived to rue the loss of his Syme stump for it is rare indeed for the midcalf below-knee stump to stand up to the wear and tear of ordinary usage the way a Syme's will do. The trouble with the below-knee stump is that with each step the whole of the weight is borne on the sloping sides of the upper end of the tibia, on skin that is unaccustomed to intermittent pressure and friction. The result is a succession of attacks of skin irritation, blistering, and ulceration. In not 1 in 10 cases can these men face anything but a sedentary life.

When the unsuitability of the midcalf operation for Canadian soldiers became apparent, all enthusiasm for reamputating Syme's stumps disappeared. It was quickly discovered that many of the defects could be overcome by doing the Syme operation over again, refashioning the flap, cutting short the nerves, and making sure that the bulbous soft tissue pad was held in correct relationship to the bones until healing occurred. Over and over again these defective stumps have been made perfect in this way and there is no doubt that before any Syme stump is amputated the possibility of repairing it should be thoroughly considered.

So unsatisfactory has the below-knee amputation proved in the Canadian army that the majority of these stumps, after a series of reamputations, removals of the fibula and excisions of neuromas have finally been converted into Gritti-Stokes above-knee end-bearing stumps. It is a pity, of course, to have to sacrifice the knee joint but experience has shown that the end-bearing thigh stump is far more serviceable to the workman than the

midcalf. Large numbers of our men with this type of amputation are working an 8 hour day at benches and machines and seldom losing a day's work.

Compared with the other amputations that of the midthigh is a great calamity. In spite of the amazingly clever artificial limb that has been devised for it, it has been found that the men are rarely able to hold any but sedentary jobs. The trouble is that they have to sit on the top of the bucket, carrying weight on skin that is not accustomed to it and with only the minimum of control over the movement of the joints. It should be performed, therefore, only as a life-saving measure.

The dictum of Ambroise Paré that a gunshot compound fracture, combined with a rupture of the main artery to the limb, calls for amputation has stood for nearly 400 years. We are wondering, however, if after all this time some exceptions may not be found to this rule. Paré was faced with the certainty of infection piled on top of the fracture and the severe injury to the circulation so that he knew that his patient's only chance depended on an immediate amputation. With early débridement of wounds, however, infection can be completely prevented in many cases and the new drugs may ultimately increase this number. It may be possible, therefore, with the aid of heparin, to restore the circulation at the time of the débridement by suture of the severed artery or to maintain it for a few days by means of a glass tube, until a collateral circulation is established. Certainly the experimental studies of Murray both on animals and on a small series of patients in hospital indicate that occasionally, particularly in air raids, when the patients can be brought quickly to hospital, such a plan of treatment might be effective.

While in this review of experiences gained in the war of 1914 I have limited myself to a very small part of the broad field of war surgery, much of what I have said has close relationship to all wounds, no matter where they may occur. What we all want to know is, first, how to prevent wounds becoming infected and, second, if they are already infected when they come into our hands, how best to combat that infection and to give our patient

will come with a silk thread, and close the wound. Ten days later the wound can be opened up and it will often be found that the ends can then be brought together without tension. Second one may introduce a nerve graft. Theoretically this should be useful for it has been done successfully in animals, but in man the results have been disappointing. In no case in which I saw it done was the result worth the trouble. However if I were working on these cases now I would try out the suggestion of using degenerated nerve as a graft and freshening the distal end and the proximal end of the distal segment of the nerve when the axis cylinders were due to pass that point. This would at least be more hopeful than the third alternative which consists of doing nothing.

AMPUTATIONS

Familiar as most surgeons are with the various types of amputations not many have had a sufficient experience to justify the formation of final opinions on all phases of the question. It happens, however that it has been the policy of the Canadian Government to bring all the amputation cases from time to time to an amputation clinic at the Government artificial limb factory at Toronto so that it has been possible for a small group of surgeons, of whom I am one to study and to follow these cases for nearly 25 years. A life history of all these patients, comprising 2,000 in all, is now being prepared by Dr. Gordon Dale and will be published soon. From our place of vantage in this clinic we have been able to observe these men not for a week or a year but for a quarter of a century. We have figuratively watched them walk down the years, slowly changing from youth to old age and we feel that we know as few can possibly have had the opportunity to know the surgery of amputation.

I shall not attempt to discuss this matter in any detail as this has recently been done elsewhere. I must point out however a few outstanding principles that it would be well to remember if it is our misfortune to have to face again the casualty lists of 1918. Almost the only reason for amputating a soldier's limb is to save his life. It is because his limb is

gangrenous or about to become gangrenous because of wildly spreading streptococcus or gas bacillus infection. It is seldom, therefore that a formal amputation of any kind is justifiable. One must content oneself with a quick circular cut, leaving the skin long so that it cannot retract above the section of the muscles and bone and leaving the wound wide open for adequate drainage. This is the so-called guillotine amputation, modified by leaving the skin long that became so popular in the casualty clearing stations and base hospitals in the old war. It was a life saver pure and simple, but it worked.

One sometimes hears this type of amputation criticized on the grounds that it takes the stump a long time to heal that it usually leaves a stump that is unsuited to fitting with an artificial limb and that it often requires re-amputation. Admitting the truth of all these criticisms, however we are still convinced that this method must be used if the mortality rate is to be kept down. Some modification of these views may come if the new bacteriostatic drugs prove helpful, but I doubt it.

It is in the reconstruction hospitals that final preparation of these patients for artificial limbs takes place and it is here that the formal amputations should be done. In the lower extremity there are only four that need concern us as the others are practically only of historical interest. They are the Syme's and the midcalf operations below the knee and the Gritti-Stokes and the midthigh above.

For nearly a hundred years the academic storms have raged about the operation of Syme. At one time it used to be the London surgeons who abused it but now it is said that Edinburgh has forsaken it and London has taken it up. Our experience has been, however that it is the best of all amputations of the lower extremity and that when well done it allows a man to stand and walk all day to follow the plough, to work in a factory or to do most of the things that a normal man can do. Twenty years ago I was put out of a squash tournament by a man who had had a Syme amputation done 15 years before. I met him the other day 35 years after his operation walking along with hardly a sign of a limp. It is our experience that if the heel flap

is well fitted on the ends of the sectioned bones, and if the nerves are cut well back, it will stand up to hard usage for a lifetime

One of the chief causes of the unpopularity of the Syme operation has been the unfriendliness towards it of the artificial limb makers. Not many of them can make a good Syme artificial limb and even when they can they dislike it because it cannot be made symmetrical with the opposite limb. The result has been that whenever a Syme stump is the least bit defective, off it comes to make way for the pretty below-knee artificial limb. Unfortunately many a man has lived to rue the loss of his Syme stump for it is rare indeed for the midcalf below-knee stump to stand up to the wear and tear of ordinary usage the way a Syme's will do. The trouble with the below-knee stump is that with each step the whole of the weight is borne on the sloping sides of the upper end of the tibia, on skin that is unaccustomed to intermittent pressure and friction. The result is a succession of attacks of skin irritation, blistering, and ulceration. In not 1 in 10 cases can these men face anything but a sedentary life.

When the unsuitability of the midcalf operation for Canadian soldiers became apparent, all enthusiasm for reamputating Syme's stumps disappeared. It was quickly discovered that many of the defects could be overcome by doing the Syme operation over again, refashioning the flap, cutting short the nerves, and making sure that the bulbous soft tissue pad was held in correct relationship to the bones until healing occurred. Over and over again these defective stumps have been made perfect in this way and there is no doubt that before any Syme stump is amputated the possibility of repairing it should be thoroughly considered.

So unsatisfactory has the below-knee amputation proved in the Canadian army that the majority of these stumps, after a series of reamputations, removals of the fibula and excisions of neuromas have finally been converted into Gritti-Stokes above-knee end-bearing stumps. It is a pity, of course, to have to sacrifice the knee joint but experience has shown that the end-bearing thigh stump is far more serviceable to the workman than the

midcalf. Large numbers of our men with this type of amputation are working an 8 hour day at benches and machines and seldom losing a day's work.

Compared with the other amputations that of the midthigh is a great calamity. In spite of the amazingly clever artificial limb that has been devised for it, it has been found that the men are rarely able to hold any but sedentary jobs. The trouble is that they have to sit on the top of the bucket, carrying weight on skin that is not accustomed to it and with only the minimum of control over the movement of the joints. It should be performed, therefore, only as a life-saving measure.

The dictum of Ambroise Paré that a gunshot compound fracture, combined with a rupture of the main artery to the limb, calls for amputation has stood for nearly 400 years. We are wondering, however, if after all this time some exceptions may not be found to this rule. Paré was faced with the certainty of infection piled on top of the fracture and the severe injury to the circulation so that he knew that his patient's only chance depended on an immediate amputation. With early débridement of wounds, however, infection can be completely prevented in many cases and the new drugs may ultimately increase this number. It may be possible, therefore, with the aid of heparin, to restore the circulation at the time of the débridement by suture of the severed artery or to maintain it for a few days by means of a glass tube, until a collateral circulation is established. While in this review of experiences gained in the war of 1914 I have limited myself to a very small part of the broad field of war surgery, much of what I have said has close relationship to all wounds, no matter where they may occur. What we all want to know is, first, how to prevent wounds becoming infected and, second, if they are already infected when they come into our hands, how best to combat that infection and to give our patient

the best chance for his life and limb. From the old war we learned or relearned the importance of splinting, débridement, and free drainage. In this war we shall have an opportunity to try out the effectiveness of chemotherapy and the use locally of the sulfonamide group of drugs. If medical experience in this war in any way resembles that of the last, however, the process of arriving at sound conclusions on these matters will be exceedingly slow. It seems to me that the information we so urgently need can come only from large scale controlled clinical experiments such as have been proposed by Meleney of New York. If for instance groups of 50 street accident cases were placed under the observation of a few trained observers and if one group were treated by débridement alone, one by débridement plus Carrel Dakin irrigation or chemotherapy or the local use of the sulfonamides or the Orr Trueta occlusion method it should be possible within a few months to settle the question of how to treat wounds. Such experiments could easily be carried out in the great hospitals of New York, Chicago and Boston supplied as they are with enormous numbers of patients and sheltered from the continuous disruptive ef-

fect of falling bombs. What a grand thing it would be for our soldiers if before the great casualty lists begin the Director General of Medical Services really knew the value of the new methods of treatment and felt himself so strongly supported by experimental and clinical evidence that he could order the adoption of those general principles that offer the greatest hope of success.

I cannot conclude my remarks without thanking you for the high honor you have done me in adding my name to the list of the distinguished surgeons who have delivered the

Oration on Surgery before the American College of Surgeons. I must confess that the word oration at first filled me with misgivings but I find that it really is a word which is used not to cramp the style of the speaker but to do honor to him. Allow me at this moment too, to assure you that the kindly and friendly spirit which has led you in this time of war to select a Canadian as your President is deeply appreciated by myself and my colleagues. The overwhelming evidence of your friendship brings comfort to all Canadians and helps them to face the future with good heart, no matter what that future may hold.

THE PROBLEMS OF SURGERY IN TOTAL WAR

With Special References to Abdominal Injuries

Temporary Surgeon Rear Admiral GORDON GORDON-TAYLOR, C B , O B E , LL D , M A ,
F R C S (Eng), London, England

I PROPOSE to make use of a certain series of abdominal injuries collected from the casualties of this war, and to employ this group of cases as a means of introduction to the consideration of certain clinical phenomena which appear to be novel in this conflict, to certain methods of treatment which are on trial, to the great value of whole blood and the blood substitutes which have been employed on an unprecedented scale in this campaign, and finally to the environment in which many of these patients have been injured or dealt with surgically.

The most prolific cause of injury throughout the centuries has been the warring instinct of mankind. Heretofore, the male has naturally been the sex almost exclusively marked out for this type of lesion, but "total war" makes no sex or age distinctions, and the experience of the Spanish war, which was utilized by Nazi and Fascist merely as a dress rehearsal for the blood bath to be commenced in the autumn of 1939, should have warned mankind of the principles and practice of the aggressors, nay assassins, who are now engaged in endeavouring to institute in Europe what has been inappropriately termed the New Order—surely a most glaring misnomer. Among the more primitive tribes it is almost unknown for the male deliberately to attack or injure the female, and in the animal kingdom it is only on the rarest occasions that the male has made an onslaught upon the female of the species. The wholesale, indiscriminate bombings, involving the lives of countless women, children, babes and sucklings which characterize "total war," forever brand those nations who first introduced and practiced this technique with the stigma of a reputation for diabolical cunning, cruelty, and sheer

blood-lust unknown in any brute or beast.

In ancient times surgeons built up their experience in the workshops of war, and war throughout the ages seems always to have served as a stimulus to advancement in surgical knowledge and craft. It is a little strange that the abdominal surgery of war should have lagged so far behind the operative treatment of similar injuries received under peacetime conditions. Six centuries have rolled past since Henri de Mondeville counselled suture of the colon and affirmed the recovery of some of those who had received wounds of the large intestine, and Ambroise Paré in the sixteenth century, writing of prolapsed and damaged intestine, pointed out that the injuries must be sutured, and evisceration reduced.

The dismal story of the lack of surgical progress in the abdominal surgery of battle, which characterized the centuries up to the period of the last great war, is well known and need hardly be reiterated. The present occasion, however, affords an opportunity for correcting at least one error respecting the history of the abdominal surgery of the war of 25 years ago. If I may be permitted to digress for a moment to the history of the abdominal surgery of that great conflict, the first abdominal operation on the Franco-British front was in fact performed in December of 1914 by the late Captain John Campbell of Liverpool, an alumnus of a famous school of abdominal surgery, the operation was a successful suture of a penetrating wound of the stomach.

The work of Owen Richards, however, really placed the abdominal surgery of warfare on its permanent sound footing. His enthusiasm and enterprise were fittingly crowned by the honor of being the first surgeon on the British Front to save an intestinal wound by means of operative surgery. On March 18, 1915, this surgeon successfully excised six feet of ileum,

perforated in twenty places in some parts the gut was so damaged that two-thirds of its circumference was torn through. The soldier was a Scotch Canadian, who after receiving the injury in a German trench, walked back to his own lines.

The third successful abdominal operation on the British Front in the last great war was performed by Claude Frankau and dealt with a gunshot wound of the colon. Here are recorded three pioneer operations: stomach, small gut colon (Campbell, Richards, Frankau).

No story of the abdominal surgery of war fare would be complete without some reference to Sir Cuthbert Wallace whose enthusiasm and staunch support for his surgeons in the British First Army in the war of 1914-1918 did so much to settle forever the curious controversy upon abatement or intervention for abdominal wounds which had occupied the minds of military surgeons so long. No quixotic fancy made me write a year or two ago St. Cuthbert must surely be adopted as the patron saint, not only of the luckless stricken in the belly by the missile of an adversary but also of all such surgeons as have a special interest in the abdominal in times of warfare.

After 2½ years of warfare it is perhaps not opportune to take stock of our experience of the abdominal war injuries of this total war and to compare and contrast the war surgery of the abdomen of two periods of time separated by a quarter of a century.

The series of 600 operations for abdominal injury in this present review comprises a most motley collection, including abdominal casualties received in naval warfare or admitted into Naval institutions, and civilians damaged by the indiscriminate air bombardments of Britain; there are also included certain Army casualties, represented by the abdominal flotsam and jetsam of the "Dunkirk miracle" and the evacuation of northern France. Still others come from the Royal Air Force and are for the most part those brought down during the epochal Battle of Britain which should be surely termed the Battle over Britain—a nomenclature which perpetuates for all time the prowess of "the few to whom so much has been owed by so many." This multifarious

group constitutes a series from which conclusions may justifiably be drawn.

In addition there are also cases of injury to the belly which have been received under circumstances more or less inseparably related to "total warfare" thus for example the "black out" has played no inconsiderable part in determining abdominal damage of this kind. Novel environment has also led to disasters, some of which involve the belly: the spleen has been ruptured through a fall on the stone floor from an air raid shelter bunk (1) by the fall of a warrior on his tin hat or of a sailor upon his gas mask. Catastrophes which befall the individual in peace may also overwhelm him in war and the circumstances of the emergency and the environment of operation may invest both with a panoply of the dramatic.

Abdominal catastrophes consequent upon disease have also been dealt with surgically under "front line conditions" perforated peptic ulcers have been dealt with successfully by operation in hospitals during air raids, and even in the woods adjacent to the Dunkirk beach. Strangulated hernias have been admitted along with air raid casualties during the blitz, and have taken their turn for operation with men and women injured by high explosives.

ABDOMINAL SERIES

Infrequency of operation. In this present conflict the abdominal surgery of war has certainly seemed conspicuous by its infrequency and the apparent paucity of numbers has impressed individual observers whose sphere of surgical activity in the Franco-British Casualty Clearing Zone so odd years ago furnished them with an abundant experience of operative aid for soldiers suffering from wounds in the abdominal area.

In Great Britain, no one hospital no single surgeon, has had so far any vast experience of these cases: they are scattered over innumerable cities, townships, villages, and hamlets throughout the land. The conditions of wounding today are of almost infinite variety and in this "total warfare" the men of the fighting forces and the civilians, the women and children, the aged and the nursing have

suffered injuries to the belly and elsewhere in circumstances as diverse as the missiles and mechanisms of destruction that have damaged, destroyed, or perhaps completely dissipated their bodies

In this "total war" a considerable percentage of the casualties from air bombardment results from crushing force or from the direct or indirect effects of "blast", in crushing injuries the abdomen is less exposed to damage than, for example, the head, shoulders, or limbs, and in lesions due to "blast" the lungs are more vulnerable than the abdomen. Experience has in fact demonstrated that, despite the stout-hearted efforts of rescue squads and the courage and devotion of ambulance drivers in cities, desperate or moribund abdominal cases do not crowd the doorsteps of our hospitals and infirmaries, and it becomes difficult to escape the conclusion that in Britain at any rate abdominal casualties able to repay surgical aid are in truth infrequent

The infrequency of abdominal operations among civilian casualties The following considerations are germane to the discussion

1 The frequency and severity of crush injuries of the trunk, including the abdomen, have been a feature of casualties on the "home front", such injuries are indubitably more mortal than penetrating wounds. Subparietal injuries of the abdomen and its contents played a relatively small part in the abdominal surgery of the last war, this time civilians, women, and children of tender years, and even the unborn babe, are suffering crush-contusions from falling masonry and from burial under collapsed houses and dwellings. Fragments or masses of wood, stone, or metal may be confusedly hurled with devastating force against the abdomen, severe visceral damage or retroperitoneal hemorrhage may be produced by "blast" without any external evidence of injury. The abdominal parietes may suffer along with the subjacent organs, and effusions of blood may be encountered in any of the layers superficial to the peritoneum. Actual rupture of the abdominal musculature along with visceral injury was infrequent in the last war, the blow that ruptured the powerful belly muscles be-

came too spent to damage the intestinal tract. The increase of destructive force nowadays destroys and damages without fine anatomical distinction

2 In towns and villages the most frightful wounds of the belly have been produced by flying glass, abdominal casualties have been eviscerated, or festoons of damaged intestine may be herniated in front and behind, along with other injuries inside the peritoneal cavity. Such are mostly beyond surgical aid.

3 Multiplicity also characterizes the wounds and damage sustained from air bombardment, not only is the mortality raised by concomitant lesions of many viscera, but many, even most of the regions of the body may be simultaneously damaged. The metal and dirt bespattered trunk and limbs in those who had been wounded by high explosives were familiar to surgeons in the last war, but the phenomenon is far more frequent in this conflict, and the severity of the accompanying injuries renders the prognosis in many an abdominal case hopeless.

4 Some of those injured in the belly may also suffer from burns of the body or limbs. This complication of abdominal injury may be encountered in ships or ashore, the prognosis will obviously become far more grave in such cases.

5 The degree of shock encountered among the casualties of this war far transcends that with which surgeons were familiar between 1914 and 1918. Despite the elaborate and highly organized resources of transfusion services, despite the transfusion of many pints of blood or plasma, despite the administration of oxygen, and all the resources of resuscitation therapy, many of the patients with abdominal injuries are past all operative assistance.

6 The clinicopathological phenomena found in men or women exposed to "blast" have been reproduced experimentally by Zuckerman (1940), who has shown that in 40 per cent of experimental animals subjected to "blast" hemorrhagic lesions are found in various abdominal organs. In the realm of human pathology and in experimental work the abdominal viscera appear to be less sensitive to "blast" than are the lungs, and ex-

perimentally in cases in which lesions are present in the belly there are also pulmonary hemorrhages. The special vulnerability of the large intestine to "blast" in the case of the experimental animal is not so marked in the case of men and women the proclivity of the small gut to exhibit lesions due to this casual mechanism is not far inferior to that of the large bowel the stomach is seldom affected. The intestine may exhibit patches of hemorrhage varying from punctiform spots under the serosa to large annular extravasations, and even rupture of the bowel has been known to occur.

The spleen may be torn in persons exposed to "blast" the liver has been bruised or torn, or its right lateral surface may be diversified by lines corresponding to the ribs the kidneys and bladder are less often implicated. Blood clot has been seen in the peritoneum and retroperitoneal hematomas, as well as effusions in the mesentery are very characteristic. Attention is specially directed to these findings in the abdomen which result from "blast," but once more it should be affirmed that the lungs are especially vulnerable to this mechanism, and that the planes of the head and neck and the nervous system may exhibit similar and perhaps extensive changes. The direct effects of "blast" are experienced close to the explosion only but the many indirect effects may produce death or serious injury at a further distance.

Nevertheless, apart from the actual nature of the abdominal wound, the "time lag" between the hour of wounding and the possibility of expert surgery in a suitable environment obviously plays a most important part in determining the fate of all abdominal casualties not immediately fatal.

The infrequency of abdominal casualties in the forces. The possibilities of the rapid collection of the wounded and their rapid and efficient transport so as to keep the "time lag" within permissible limits must vary with the naval or the military situation. The time factor may be inevitably protracted to the grave disadvantage of the patient by the vastness of the intervening expanse of sea or air.

In army warfare a prolonged time lag should not be so inevitable or capricious save

in circumstances of retirement, since hospitals reserved for the treatment of abdominal and other cases of first urgency should be so mobile that they can be kept within the permissible time lag despite the rapid movements which nowadays characterize war. Alternatively under certain conditions air transport can surely bring surgeon and patient together with the least sacrifice of important hours.

It is manifestly impossible to maintain forward hospitals in an army falling backward especially under conditions of rapid retreat. All patients operated upon before the "break through" must be sent far rearward and for the most recent casualties little more than first aid treatment is possible before evacuation. Such untoward circumstances obviously preclude the possibility of recovery for any large percentage of abdominal cases those that survive owe more to their own physical stamina and stoical fortitude than to the exuberant optimism and enterprise of the surgeon. Abdominal casualties certainly survived the retreat of Gough's Fifth Army in March 1918 and also the more recent Dunkirk evacuation.

In the first clash between the British forces and the enemy across the Channel in May 1940, the military situation precluded the successful performance of abdominal surgery save on a small scale. Cases are known to me of abdominal injuries received during this period of very mobile warfare in which patients were operated upon in France and Flanders, were rapidly embarked at Dunkirk and other French ports and completed their recovery in England. For example, Major W. E. Underwood R.A.M.C. had several successful abdominal cases at this time.

Nowadays, the conveyance of British wounded in hospital ships under the aegis of the Red Cross carried special dangers. Abdominal casualties during transportation across the Channel and the high seas have shared with other injured men the mental torture and perhaps further physical agony from deliberate bombardment of the Red Cross.

In this war the chances of recovery of an abdominal case from such an outrage have been prejudiced still further by the air bom-

bardment of wounded men in the water, a practice which has been freely indulged in by the German and Italian even upon Axis allies, and few that had already been wounded in the belly can have survived

By reason of the environment in which naval casualties are inflicted and the nature of the missiles employed, abdominal wounds are very fatal in ships, although some splendid results have in fact been obtained in men wounded at sea, or even in the sea, during this present conflict. Surgeon-Lieutenant Donald, R N, performed a laparotomy in one of H M Destroyers, when the "naval situation" was such that there was no prospect of transference of the man to a hospital ship or ashore. Unfortunately, the cecum and ascending colon proved to be gravely damaged, with extensive contamination of the peritoneal cavity with liquid fecal material, the man succumbed. An injury to the small bowel might have held out a better hope of recovery.

Immersion in the sea after shipwreck has on occasion been associated with a less familiar abdominal injury, to which Surgeon Commander Rex Williams, R N, has given the name "immersion blast." This will be referred to later in the author's forthcoming Bradshaw Lecture and in Rex Williams' Hunterian Lecture in 1942.

Nowadays there is no safe sanctuary anywhere for the wounded, even in the hospitals and infirmaries of our cities. Wounds from enemy aircraft may even supervene upon medical illness, the Boche never hesitates to hit again when man, woman, or child is down. The destruction of hospital buildings may withdraw from the wounded man the hand stretched out to save him, every hospital in London except two has been hit by indiscriminate air bombardment. A police inspector had been wounded by a bomb splinter which had entered the right flank, presumably damaging some intraperitoneal organ. He was placed upon plasma infusion which rallied him, and the man would without a doubt have been able to be operated upon, unfortunately, the hospital was badly damaged with loss of life to nursing sisters and others, and it became impossible to operate or for a time to evacuate. The man succumbed.

Sex In figures culled from air raid casualties in Great Britain, there is no striking difference in incidence between the sexes. However in one series of abdominal cases in which I have taken particular interest, but *which is a motley collection*, 78 per cent were men, 20 per cent women, and 2 per cent children. Nine of 11 of the infants injured in this series were girls.

Age The youngest victim in this abdominal series to survive an intraperitoneal injury due to enemy action was aged 3 years, this was a subparietal lesion. The next youngest to survive were 7, 8, and 9 years of age, respectively, the mortality in babyhood and early childhood is extreme, although a baby of 10 months recovered from a through-and-through wound of the abdominal wall, which did not implicate the peritoneal cavity.

The following cases perhaps emphasize the horrors of the modern technique of air attack introduced by the totalitarian powers.

A girl of 11 years walked into a hospital, close to which she had been injured by a bomb splinter. She had a penetrating wound of the abdomen situated near the right costal margin and bleeding profusely. At operation, no injury to the gut was found, but there was a severe tear of the right lobe of the liver. The tear was partly sutured and also packed. Despite every form of treatment the wounded girl continued to bleed, and died 24 hours after operation.

The injury from which a little girl of 3 years made a recovery was a subparietal lesion and probably involved an injury to the common bile duct. Her life had been despaired of for several days after she had been rescued from a house in a row which had been completely demolished, she then developed a huge collection of bile in the lower part of the belly, this was drained and convalescence was then straightforward.

A girl of 8 years was an in-patient of a hospital for an operation for cleft palate. During her stay in hospital, the building was badly bombed by Huns, and she received a small perforating wound near the middle line at the level of the third lumbar vertebra. She was hurriedly removed from the damaged building to another institution, and two perforations in the sigmoid flexure were sutured. A proximal colostomy was performed. Recovery took place.

A boy of 9 recovered from a frightful left-sided abdominothoracic injury in which his stomach was protruding from the wound (Alcock).

The youngest living thing known to be destroyed in the maternal womb was a fetus of 6 centimeters! A woman was in an air raid shelter which was destroyed and was thought to present the clinical

picture of blast injury to the lungs. After 48 hours, she succumbed, and at the autopsy the clinical diagnosis was confirmed by the pulmonary changes demonstrable. She had also a large retroperitoneal hematoma, especially marked in the perinephric regions; there was an extensive blood infiltration of the mesentery which had encircled the bowel under its serous coat in several annular patches. The uterine cavity contained some blood, and there was a partial separation of the placenta from the uterine wall. The fetus measured 6 centimeters in length, and showed bruise on its anterior abdominal wall—surely the earliest living thing to receive a blast injury.

After 12 years of age, the prognosis seems to be less dismal.

A girl of 13 was running in the open to an air raid shelter when she was struck by a flying piece of metal. She had a punctured wound of the left para-umbilical region, through which some omentum had been extruded. At the operation (Mr. Donald Thompson) tests were found in the small bowel and transverse colon. The missile was extracted from the rent in the large bowel. The gut injuries were treated by suture. An uninterrupted recovery took place.

Phoebe C., 15 years of age, was admitted to hospital in a state of extreme shock resulting from wounds received from bomb splinters. There were multiple wounds of the back, and a large laceration of the left buttock tracking up between the sacrum and ischium and penetrating the abdominal cavity. Ten hours elapsed before she could be made fit for surgical exploration of the abdomen. She had 7 perforations of the small gut. A large piece of metal was removed. Recovery took place (Mr. Lloyd case).

At the other extreme of life *old age* although naturally increasing risk, does not preclude recovery.

Male 7 years, received penetrating wound of abdomen 3 perforations of small bowel lacerated wounds of scalp and left eyelid, fractures of face, scalp, and hands (Mr. Southern case). This man, despite his years, made surprisingly good convalescence. A plastic operation upon his scalp was successfully performed month later.

Annie M. aged 73 recovered from left-sided abdominothoracic wound fortunately no abdominal viscus was injured. The woman, however, had fracture of the fourth rib on the left side and there were lacerations of the right forearm, right breast, and left elbow.

Abdominal injuries of total war" and pregnancy. It is a ghastly commentary on Nazi *Kultur* that their deeds should have made the record of the following cases possible.

E. S. 30, married, 4 months pregnant, received bomb injury of the abdomen. The severe lacerations

of right arm were excised and treated by local chemotherapy. There was also a wound in the right iliac fossa. A glass splinter 3 inches by 1 inch was found lying loose on the cecum; no internal organ was damaged. The abdomen was closed without drainage. It was just too bad that the patient did not miscarry (Major Rodney Smith case).

A married woman 5 months pregnant, injured by the explosion of a bomb close proximity but never attained condition permitting operation. The fragment had entered the left labium major, fractured the left ascending ramus of the pelvis, driving a fragment of bone into the bladder; the missile then traversed the pregnant uterus, entered the cecum, and was finally arrested in the right sacro-iliac articulation. Her daughter aged 7 years, simultaneously received right-sided abdominothoracic wound implicating lung, diaphragm, and liver; the girl recovered.

A woman of years 8 months pregnant, admitted to hospital with bomb splinter wound of the left side of the abdomen, through which part of the omentum was protruding. Shock as profound. At operation (Mr. G. H. Balnes case) several perforations of the small intestine were sutured; considerable intraperitoneal hemorrhage was present. A view of the patient's desperate condition the abdomen was closed with through-and-through sutures as hastily as possible. Stillbirth took place the following day. For the first week following operation the pulse ranged round 20 the abdomen as greatly distended. On the tenth day the patient had pulmonary embolism. After this, convalescence smoother although protracted, and she was finally discharged from hospital on the seventeenth day.

A woman, 9 months pregnant, was admitted to hospital with multiple injuries which resulted from bomb explosion. The left buttock was completely destroyed; a piece of omentum was hanging out of wound in the belly wall. The patient died without operation.

A woman of about 35 years, 9 months pregnant, was admitted to hospital gravely ill, with a severe fracture of the skull from which brain matter protruded. Shock was extreme; the fetal heart sounds were still audible. It was apparent that the patient was going to die, and the question of cesarean section was mooted. The prospective father and every member of the family had been killed by the same incident, and no operation was performed.

Abdominal injury due to enemy action during parturition. Enemy air raid activity may not only produce abdominal injury in the parturient woman but naturally injuries in other parts of the body may be produced.

The good fortune so far as loss of life is concerned of the well known historical maternity hospitals in London has been remarkable. All have suffered as a result of enemy

action, but no patient has actually been killed within their walls. In another institution the abdominal wall of a patient was ruptured during labor pains, as the result of "blast."

Alice G., aged 36 years, 9 months pregnant multipara, was in the maternity department of a hospital. She complained of labor pains one afternoon, and by evening the pains were strong and frequent. During a severe air raid at night, when several flares lit up the building, she got out of bed and walked along the corridor. At this moment a heavy bomb fell in the hospital grounds about 150 yards from the maternity ward, and all the windows and most of the ceilings in that portion of the hospital were damaged.

The patient collapsed, and examination revealed a loop of transverse colon protruding from a rent in the upper abdomen. This wound was vertical, 4 inches long, and situated over the outer border of the right rectus, the edges were clean cut and bloodless, the bowel was not perforated. There was no evidence of her nightgown having been torn by bomb splinters or glass. A forceps delivery was performed 3 hours after the incident, and a stillborn female child was obtained, the extruded bowel was then replaced. Despite every form of resuscitation the patient died 2 hours later.

Nature of projectile producing injuries. In discussing the nature of the projectiles, it has already been emphasized that many of the injuries received from air bombardment are subparietal or nonpenetrating in character. In the majority of the series of abdominal cases which were selected for special study, a fragment of bomb casing has been the projectile. Certainly in no abdominal case has a large retained fragment of metal been encountered, the largest retained fragment in a patient who recovered was the size of a walnut. In a number of cases the injuries have been produced by bullets. On the whole, these have done well. The increased use of the incendiary bullet adds to destruction and necrosis of tissue produced by burning, in the case of the intestine this may demand resection, where suture would otherwise have sufficed. The recovery rate of those injured by the revolver bullet is flattering to the surgeon.

The destructive effects of flying glass in air bombardments are nowadays familiar to most surgeons. It suffices merely to mention the tragic facial disfigurements in women, the damage or loss of eyes, while in the abdomen coils of intestine may be cut to pieces within

the belly, or may hang out of dreadful gashes in the chest or abdominal wall. A man admitted to hospital wounded by a long spicule of plate glass had the hepatic flexure of the colon and a coil of small gut completely divided, his right kidney was cut in sunder, and the continuity of the renal vessels at the hilum, the man died despite operation.

Small puncture wounds produced by glass may betray catastrophic lesions within. A blood stain on a woman's night dress revealed a small punctured wound in the epigastrium. On wiping away a clot which had temporarily sealed the small wound, a column of blood a foot high spurted upward. A splinter of glass of the size of the index finger was withdrawn from the liver. The patient succumbed.

Sometimes visceral injury produced by glass is less severe, and lesions of the bowel have been successfully treated by surgery. Sometimes, there may even be peritoneal penetration, without visceral damage.

A patient may be wounded by glass and bomb splinter, for example, a man had numerous punctured wounds all over the body due to glass, one tiny puncture was situated just below the left costal margin. There was no shock, but lower abdominal pain and infinite tenderness below the umbilicus.

Operation was performed by Mr. Meyrick Thomas and Mr. Desmond Cooper. After excision of the wound, when the track was followed inward, it appeared definitely to end at the level of the external oblique aponeurosis. However, when this was incised the track was found to pass through the internal oblique and transversalis, and a tiny puncture wound in the peritoneum. The peritoneal cavity contained a quantity of blood, small wounds in the anterior and posterior walls of the stomach were sutured, a small retroperitoneal hematoma was found, and a spurting artery in the position of the coronary artery where it was just leaving the posterior abdominal wall to enter the lesser omentum. Subsequent x-ray examination showed a small dense fragment low down at the level of the lumbosacral junction. Recovery took place.

A man received a double injury under unusual circumstances. When milking a cow, he was hit in the upper part of the buttock by a bomb splinter and gored in the thigh by the animal! He was found to have two perforations of the small bowel, which were sutured, the cecum was "grooved," but not perforated. There was a wound of the right anterolateral surface of the bladder, and the fragment was found in the

cavities. The thigh wound inflicted by the cow was very extensive. The man made a good recovery (Mr M. D. Shepherd's case).

In addition to glass fragments, debris stones, and mud other foreign bodies may be met along with bomb fragments.

A man standing in the street received abdominal injuries from a bomb splinter: the wound of entry was situated under the left costal margin, the wound of exit in the lumbar region; the left of the spine. Operation revealed a complete severance of the transverse colon, a bomb splinter and penaeus (?) were removed from the track. Unfortunately the man died.

Viscera may be damaged by in-driven bone fragments, although the missile itself does not penetrate the peritoneal cavity. This has happened especially with fractures of the innominate bone, sacrum ribs, etc.

Hollow viscera have been punctured by metal fragments which have not penetrated the peritoneal cavity. Cases of bowel injury by indirect violence were reported by Owen Richards, Sir John Fraser and others in the last great war. One such case had both recti abdominis almost completely divided by a through and through wound which was explored and the peritoneum was found intact. Nevertheless, the man succumbed and 3 lacerations in the small intestine were present. The injured piece of bowel lay immediately underneath the wound of the abdominal parietes. Similar cases have been met with in this war for example:

E. V. female aged 43 years, was admitted to hospital half an hour after being wounded by high explosive bomb. On admission, shock was found to be only mild, there was a deep laceration of the right groin just below Poupert's ligament, which appeared to involve the tissues behind the ligament and also the extraperitoneal structures of the right iliac fossa. There was no wound of the abdominal wall itself and no evidence of first of an intra-abdominal lesion. Three hours later tenderness and rigidity had developed on the right side of the abdomen and laparotomy was now clearly indicated. At operation (Mr Wass) it was definitely established that no communication existed between the wound in the groin and the pelvic cavity. Nevertheless 3 perforations of the lower ileum were found to be present.

There are only two bayonet wounds in this series.

An enemy agent, during the Dunkirk evacuation, was bayoneted through the right lower chest in the

black-out. There was a lacerated wound of entry over the ninth right rib, which was fractured; the wound of exit was situated in the right hypochondrium anteriorly. There was considerable abdominal tenderness, but apart from the excision of the wounds of entry and exit, the man was treated on conservative lines. He recovered (Major A. S. Tait's case).

F. P. (Mr J. S. Horn's case) aged 24 years, a soldier, was sent to hospital with the history that he had fallen on his bayonet while in practice. The bayonet had been removed from the left ischiofemoral fossa where it had entered, and a stitch had been put in the skin as the bleeding had been profuse. There was a small exit wound in the left subcostal region. He was very shocked and given a pint of citrated plasma, followed by a drip transfusion which was continued during the operation. At laparotomy the spleen and left kidney were found to be uninjured, but there was a small hole leading from the peritoneal cavity into the base of the bladder. The bladder was therefore opened, and an attempt was made to suture it, after which both the bladder and the peritoneal cavity were closed with drainage. The wound in the buttock was sprayed with sulfamide powder and drained, as was also the wound in the side. After somewhat stormy convalescence, he recovered.

Immunity of viscera in penetrating injuries of the abdomen. The occasional immunity of viscera in penetrating wounds of the abdomen first suggested in the South African War confirmed in the last great war has again been re-established.

Spontaneous recovery from indubitable wounds of the hollow viscera which was demonstrated by Makins, Cuthbert Wallace, Green-Armytage, Gordon Bell among British surgeons in the last great war has been confirmed by the experience of today.

The buttock wound. In 59.6 per cent of penetrating wounds of the belly the wound of entry is anterior. In 40.4 per cent, the wound of entry is on the posterior aspect of the body. In half of these (20 per cent of total) the wound is in the buttock. The dangers of overlooking the buttock wound were stressed in the last war: the great frequency with which this constitutes the portal to the peritoneum emphasizes the necessity of completely stripping the patient and the most thorough examination of the whole body.

J. S. (Mr Greening's case) aged 3 years, dactylitis, had been treated intermittently for syphilis since 1937. In the beginning of 1944 her Wassermann

was ++, and she was under treatment when she was wounded by a fragment of bomb. The patient, in addition to intravenous injections, had also received a very large number of injections of bismuth in the buttocks. On January 11, 1941, it was the left buttock that the missile entered, passing upward and across the abdomen to the right iliac fossa. She made a satisfactory recovery from an operation which comprised a resection of 6 inches of ileum and the suture of two other perforations of this portion of bowel as well as the suture of a wound in the bladder. Her courage and pluck were such as to stimulate her to return to the "West End of London" 4 weeks after her operation. She had discharged herself from hospital against surgical advice. Subsequently, she required treatment for the removal of sequestra from the innominate bone and for an infection of her bladder with *Bacillus coli* and *Bacillus proteus*.

Direction of missile track. Wounds which track across the abdomen from side to side enjoy a more sinister reputation than those whose direction is anteroposterior.

The case of a very successful result is recorded as follows:

A member of the Home Guard (Mr I. H. Bentley's case) was accidentally shot through the abdomen by a rifle bullet, sustaining 13 perforations in small intestine. The abdomen was opened 4 hours after the injury, and after the intravenous administration of 2 pints of blood and was found to be completely filled with blood. The bullet had splintered the ilium and was lodged in the left iliacus, the hemorrhage had largely proceeded from the laceration of the pelvic mesocolon. The continuity of the small bowel after resection of 4 feet of damaged jejunum was effected by an end-to-end junction. An uninterrupted recovery ensued.

The vertical wound track had also a bad reputation in the last war, many specimens in the former collection at the Royal College of Surgeons illustrated the truth of this statement.

A case with a successful outcome occurs in this present series.

A woman, Ethel K., received a penetrating wound of the left buttock. An x-ray film showed the presence of the fragment high up under the cupola of the diaphragm. There was a quantity of blood in the celom, and there was much retroperitoneal bruising, and hemorrhage in the left iliac fossa. Two perforations of the jejunum were sutured. The patient made a good recovery.

The large wound involving one of the cavities of the body is nearly always fatal, the man with a large wound of the abdomen or a wide loss of the abdominal wall seldom recovers.

A patient was admitted to hospital with an extensive abdominothoracic injury, including a large

perforating wound, 8 by 4 inches in the left lower chest and left hypochondrium, associated with a pneumohemothorax, a lacerated diaphragm, and a perforation of the splenic flexure of the colon, he lived 5 days after operation, dying of pneumonia. The lower 6 ribs were fractured on the left side, and the fractures were implicated in the huge wound. There was also a second wound of the thoracic wall 3 by 3 inches which involved only skin and muscle. The capsule of a sclerotic spleen was torn, but had not occasioned hemorrhage, no treatment for this was needed. The torn diaphragm was sutured to the parietes with improvement in respiration and general condition. The dimensions of the wound and loss of tissue precluded its complete closure.

A man admitted to hospital after injury from a bomb had the anterior abdominal wall, including the peritoneum, completely torn away. Numerous pieces of rubble of varying size covered the presenting intestinal coils. There was a complete rupture of the transverse colon and several perforations of the jejunum. Mr Desmond Cooper, working at top speed, brought the two ends of the damaged colon to the surface, sutured the perforations of the small gut and made a gallant attempt to close as much as possible of the anterior abdominal hiatus. Despite the fact that the operation was completed in 15 minutes and all the resources of transfusion therapy employed, the patient succumbed.

This dismal story might be told and re-told almost indefinitely, nevertheless, some wonderful recoveries have taken place and constitute veritable triumphs of surgical skill.

Mr Arnold Alcock's case is perhaps specially remarkable, inasmuch as the boy was only 9 years of age.

A boy of 9 years was admitted to hospital with a large wound 8 inches long in the lower part of the left thorax, fifth, sixth, seventh, eighth, and ninth ribs were splintered, and there was a tear in the diaphragm 4 inches long. From this traumatic chasm the stomach protruded, there was a small puncture wound on the lesser curvature which was fortunately not large enough to permit the contents of the replete viscus to flood the thoracic and abdominal cavities. There were also several incomplete tears of the gastric wall, produced by the fractured ribs. The lung appeared undamaged. The perforation in the stomach was enlarged, and a mass of undigested vegetables emptied from its cavity, the gastric wound was sutured. After a thorough excision of the wound, the diaphragm was sutured, and the thoracic wall closed, a Malecot catheter was introduced into the pleura through a separate incision posteriorly. After an anxious week, the patient's progress was maintained and he made a good recovery.

A seaman (Mr John A. McLauchlan's case), of 40 years of age was admitted to hospital for injuries due to a bomb fragment. There was a large wound, 8

foches long, over the eighth, ninth, and tenth ribs on the right side just above the costal margin. The seventh to eleventh ribs inclusive were fractured and at re-in. The pleural cavity was opened, the diaphragm torn, the upper surface of the liver lacerated, and the upper pole of the right kidney punctured. The wound was excised, the liver sutured, diaphragm repacked. The jagged and comminuted ends of the broken ribs were removed, and the diaphragm was attached to the thoracic wall above the rent. The chest was closed by layers. Recovery took place.

Nonpenetrating or subparietal abdominal injuries. Careful postmortem investigation disproves the belief that fatal casualties without external wound are frequently abdominal injuries. In only about 10 per cent of all fatal casualties in one series of cases could death be attributed to an abdominal lesion; a primary blast effect could only be impugned as the causal mechanism in a tiny fraction of these. Most of the abdominal lesions among these fatal cases were caused by collapse of buildings, and crushing injuries or by blows upon the belly by flying missiles or portions of collapsing buildings. Injury to the spleen was the most frequent form of visceral damage to occasion a fatal issue but the liver, kidney, duodenum, and small bowel were also damaged in mortal injuries and in 1 case hemorrhage from the uterine vessels caused a fatal hemoperitoneum.

In casualties due to air bombardment of cities, many of the injuries are not the primary effects of the explosion, i.e. are not produced by splinters or the direct impact of a blast wave. Perhaps most casualties are due to the secondary and tertiary effects of the bomb detonation.

Those effects are said to be secondary when injuries are due to the patient being bowled over by the blast wave or as a result of a splinter wound and thus injuring himself (Zuckerman). Tertiary effects are due to the impact of dislodged masonry fragments

causal mechanisms operating in cases of parietal abdominal injury met with in war.

A patient, woman of 33 years, was blown blast across a room against a steel partition building then collapsed on her crushing her under down into a crouching position. Release effected in about half an hour after the incident. Contusion of the lung, possibly due to blast diagnosed. I view of the thoracic condition, abdomen was most wisely opened under local anesthesia. The pelvic hematoma was found to be stripped the peritoneum half way up the abdomen. The anterior wall of the bladder great broad suprapubic drainage was instituted pure blood previously been obtained on catheterization. (valence was complicated by consolidation of left lung, paralytic ileus and by temporary ileus). Ultimate recovery was complete (Miss Lord case).

The abdomen of another patient has been severely contused by flying bricks from a direct hit by bomb on a street air raid shelter. She had perforations of the jejunum, which were successfully sutured, a hematoma of the mesentery was also evacuated.

Under similar circumstances, a woman had ovarian cyst ruptured. 4 pints of blood-stained fluid were evacuated from the abdominal cavity and sac of the torn tumor was removed. Recovery took place.

The collapse of the roof of a house which had craved direct hit produced a complete division of the jejunum in a man of 6 who recovered after end-to-end suture of the bowel.

A crush injury due to collapse of wall produced separation of the pubic bones at the symphysis, fracture of the humerus posteriorly but had also the mesentery of the terminal small gut. The laceration was transverse and two arteries were still spurting at the time of operation. The bowel was viable and made good recovery.

Winifred C. aged 25 years, was admitted to hospital for injuries sustained when her house collapsed upon her and piece of concrete fell across abdomen. Her injuries included multiple abrasions on the face, 3 deep wounds of the scalp extending down to the bone, deep wound of the medial aspect of the left knee which did not implicate the joint and wound over the left olecranon. An indefinite

tion of mines at sea, the exact mechanism has not always been evident, in some cases decks have actually fallen in and exerted a crushing effect

A man was admitted from a "mined" ship, the galley in which he worked caved in upon him. In addition to burns of both hands, he had a diastasis of the symphysis pubis, and a fracture of ascending and descending pubic rami. A small extraperitoneal rupture of the bladder was present, and there was urinary extravasation into the Cave of Retzius. Post-operative ileus complicated his convalescence, but he ultimately made a good recovery (Mr W E C Wynne's case).

Another man admitted from a mined ship had a fracture dislocation of the knee and evidence of abdominal injury. He had been in the water some time before being picked up. There was gross bruising of the transverse mesocolon, and also numerous petechiae on the bowel wall. The right kidney was contused. The limb required amputation, but the man recovered (Mr W E C Wynne's case).

Some abdominal injuries have definitely appeared to have been caused by blast. Mr D H Patey had 1 case, in which a man running away from a bomb was exposed to the blast wave. There was no sign of any external injury and no history of any blow from any fragment of timber or masonry. His mesocolon was torn in the vicinity of the splenic flexure of the colon with resultant hemorrhage.

Another case was that of an intramural thrombosis of the blood vessels of the right side of colon (Mr Blacon Yates' case).

P H, male, aged 38 years, was admitted to hospital in a state of extreme shock, he had been in close proximity to a detonating bomb, although the exact distance which separated him from the missile was never actually determined. Abdominal pain was not marked, 1,000 cubic centimeters of plasma was first administered by drip transfusion, then a pint of blood, followed by 600 cubic centimeters of 5 per cent glucose saline. His general condition slowly improved, 24 hours after admission the abdominal pain became more severe, especially on the left side of the abdomen. At 30 hours, clinical evidence of diffuse peritonitis was apparent, and laparotomy was performed. The only visceral lesion discovered was gangrene of the anterior surface of the cecum and proximal 2 inches of the ascending colon. The condition appeared to be due to intramural thrombosis of the vessels of the bowel wall, the vessels of the mesentery were quite normal.

W J L, under the care of Mr H Donovan, succumbed from subparietal injury, this case definitely

appears to be one of blast injury to the abdomen. The thoracic pathological findings confirmed the nature of the causative mechanism, the liver showed intrahepatic tears and hemorrhage, and a large subcapsular hematoma. The right suprarenal also contained a hematoma. The inferior pole of the cecum contained a small hematoma, the ascending and transverse colon exhibited marked bruising. There was a tear in the seromuscular tunics of the transverse colon.

In Mr Hamilton Barclay's case, a man was in the open when a high explosive bomb detonated in close proximity to him. He had not been struck by any fragment, nor fallen on his belly. There was a large hematoma of the great omentum, and a certain degree of hemoperitoneum. An extensive retroperitoneal hematoma was present, and a horizontal rupture of the abdominal wall, the tear extending from the peritoneum through the muscular wall of the parietes to the skin, which was intact.

In respect to injuries due to blast, it must be remembered that "blast injury of the lungs" by reason of the abdominal pain produced may suggest the diagnosis of an abdominal lesion. Some of these patients have rigid abdominal walls, possibly the pain and rigidity may be caused by hemorrhage in the thoracic intercostal spaces.

X-ray examination of the chest should enable a diagnosis to be made of pulmonary concussion, and the physical signs in the chest, especially the bulging of the chest wall, should prevent an unnecessary laparotomy.

Nonpenetrating or subparietal injuries of the abdominal viscera may occur under circumstances less directly connected with the destructive mechanisms and missiles of total warfare. The "black-out" is a fruitful source of such mishaps, their name is legion and their variety infinite.

The subject of "*Immersion Blast*" is being dealt with by Surgeon-Commander Rex Williams R N in his Hunterian Lecture in 1942, and also by the writer in his Bradshaw Lecture for 1942.

Lesions of the stomach in "total" warfare. This war has added little to our knowledge of penetrating wounds of the stomach. Operations for wounds of the stomach have given a recovery rate of 60 per cent in this series from the present war, this is a marked advance from 36.3 per cent in the last war (Cuthbert Wallace). Wounds are of infinite

variety depending on the size, shape and velocity of the missile the direction of its flight the state of the stomach in respect to repletion or vacuity etc. In some cases, the wounds have been wide and gaping in a wounded man coming under the care of Mr Blacow 3 days the wound in the stomach was 4 inches long and the mucous membrane was extensively everted In another patient operated upon by Surgeon Lieutenant-Commander B C Murless, R.N.V.R. the gastric rent extended from the esophageal opening to the greater curvature. In a successful case of Mr J Scholefield, the stomach wound was 3 inches long

Eversion of the inner tunics of the stomach wall was said in the last war to be most marked at the curvatures and in wounds of considerable dimensions. In the present series of cases under review no mention is made of the note of exclamation wound, to which Sir Cuthbert Wallace drew attention. In several of the recent cases, severe hemorrhage has taken place into the celomic cavity

There is one condition of the stomach which has impressed by the striking frequency of its occurrence in this war—*acute dilatation of the stomach*. Not only has this phenomenon been a concomitant of penetrating injury of the abdomen but it has also proved an undeniable and sometimes intractable sequel of operations undertaken to repair the damage inflicted by the detonation of bombs from enemy aircraft.

H. H., male aged 35 years, was injured by bomb fragment there were multiple flesh wounds of left thigh, buttocks and epigastrium. An exploratory laparotomy revealed no visceral injury the patient had to be prematurely evacuated to base hospital, where he arrived very ill and shocked and was found to be suffering from acute dilatation of the stomach. This was relieved by continuous suction drainage intravenous infusion promoted satisfactory convalescence

A girl of 7 was in the kitchen of a house which received direct hit from a bomb the house came down on top of her father (who died shortly after admission to Hospital) her mother and two day old baby (who both recovered) and herself. She was moderately shocked extensive bruising of the pubic region and chest was present. Radiography showed fractures of the ischium and pubes on the right side and of both rami of the pubis on the left side. The radiologist commented upon the condition of

acute dilatation of the stomach. At operation, an extraperitoneal rupture of the urinary bladder was found. Despite suction drainage of the stomach the gastric condition never ameliorated, and she succumbed 66 hours after operation.

Surgeon-Commander Rex Williams, R.N. in private communication mentions a case of penetrating wound of the abdomen that died on the sixth day from acute dilatation of the stomach, despite every effort to control the complication

Acute dilatation of the stomach may supervene at a still later date after wounding, may defy all treatment, and may determine a fatal ending

A patient was admitted to hospital for injuries from bomb explosion occurring few minutes before. Shock was profound the patient was very pale, cold, clammy apathetic, but not restless. There was gross compound fracture of the upper third of the left femur and there were sucking entry and exit wounds of the right chest. After period of resuscitation lasting 4 hours, during which 4½ pints of blood were administered, the patient's injuries were dealt with simultaneously by two surgeons. Mr Kilpatrick performed a debridement of the thigh wound, and the limb was placed on a Thomas's splint with skeletal traction. The abdominal thoracic injury was admirably treated by M. Wans. There was no sound of the lung, but sound in the diaphragm and liver. He was evacuated to base hospital 9 days after his injury. Six days after his admission to base hospital he became very ill temperature 100 degrees pulse 100-120 the chest condition was considered satisfactory. He had been vomiting bile stained material for the previous 3 days but there was no clinical evidence of dilated stomach. A stomach tube was introduced and left in *situ* despite this vomiting persisted, and he died 6 days after he was wounded. The postmortem revealed the presence of an *acute dilatation of the stomach* few cubic centimeters of blood were present between the liver and diaphragm. The chest wound was healed and the state of lungs and pleura was considered satisfactory

Mr N R. Barrett and Mr Price-Thomas have drawn by attention to the *sudden acute dilatation of the stomach which frequently takes place in contusions of the chest*

Perforation of peptic ulcer The circumstances under which perforation of a peptic ulcer may occur and operation be undertaken for its repair may invest a mundane occurrence and a banal surgical procedure with a dramatic color

Several ulcers are known to have perforated during air raids on the country and several have been operated upon during the "blitz"

A male patient, T D, perforated a duodenal ulcer during progress of an air raid on Merseyside and was removed to Hospital, operation for its repair was in progress, when the hospital got a direct hit, putting the operating theater department completely out of action. The laparotomy wound was temporarily closed, the patient removed to another institution, where the operation was completed by the resident surgical officer, the man recovered.

Another patient was being operated upon for a perforated duodenal ulcer when the detonation of a mine in close proximity brought the roof of the theater with superjacent sandbags down upon patient and those engaged in the operative relief of his condition. The emergency lighting system fortunately proved itself worthy of its name, and the operation could be continued. The debris, glass, dust, and sand were assiduously removed from the abdominal cavity, the perforation was sutured. The man made a good recovery, his only complaint being of "the dust in his eyes."

A rear-gunner in a Blenheim bomber perforated a duodenal ulcer over Dunkirk, he thought that he had been wounded by "Flak." On the return of the aircraft he was admitted to hospital as a casualty from enemy action, no wound was discoverable. The real condition was then diagnosed, and the patient successfully operated upon by Group Captain Stanford Cade.

I have knowledge of at least 3 ulcers which perforated during the "Dunkirk miracle," in which recovery took place. The number of loyal stout-hearted men who, weary though they were, contributed in diverse fashions to the ultimate recovery of their comrades cannot have been inconsiderable.

Intestinal injuries The recovery rate of intestinal injuries due to enemy action which are operable has surprised me. Of the patients with small bowel lesions 47 per cent have recovered, and 40 per cent of those with large gut lacerations. Suture carries a lower mortality than resection for wounds of the small intestine and should be preferred whenever possible. This doctrine, as the perusal of case records clearly demonstrates, is firmly inculcated in the minds of British surgeons, in the Spanish War operators seemed disposed to resect when the ileum was the segment of bowel damaged and to suture when the jejunum was involved. The type of resection

and anastomosis employed is a matter of individual choice and experience, and is not a fashion which varies from war to war. My predilection led me to use end-to-end suture in the last war in every intestinal injury in which bowel resection was indicated.

The specter of the "dangerous mesenteric angle" was permanently robbed of its terrors in the light of the experience of the last war, since no case was found to demonstrate that fatal peritonitis was ever due to leakage at that angle. Peritonitis was invariably due to infection introduced with the missile at the time of wounding or subsequently from the injured gastrointestinal tract, especially the large gut, and was in no way causally related to the technique of bowel anastomosis. Lengthy resections of small intestine imply severe and widespread wounding, the ablation of short segments of gut is therefore more promising. Nevertheless, the removal of 6 feet of small intestine and the cobbling of other injuries proved successful in the last war (Owen Richards, Gordon Bell, Gordon-Taylor), in this war Surgeon Commander T N D'Arcy, R N, saved a 6-foot resection of small bowel severely damaged and burned by a phosphorus bullet, F H Bentley, a 4-foot resection.

I have sometimes been credited with the advocacy of resection as opposed to suture in cases of injuries to the colon produced by enemy action. This is far removed from the truth. There can be no doubt about the place of suture in most intraperitoneal colon wounds, and also about the indication for suture in conjunction with efficient drainage of the neighboring area in many extraperitoneal injuries when this technique offers a reasonable prospect of success, suture, local chemotherapy, and drainage of the damaged area may be combined with proximal colostomy in cases in which grave infection is feared.

Colostomy sometimes proved valuable in the last great war as a prophylactic measure against infection of the lethal retroperitoneal tissues, if this operation is performed, it should be practiced early, before infection has secured a firm hold of the region. Sulfonamide therapy, local and oral, has already proved a valuable adjuvant to surgery for patients with damaged large intestine, and its routine use prophylac-

Sulfonamide therapy, local and oral, has already proved a valuable adjuvant to surgery for patients with damaged large intestine, and its routine use prophylac-

¹A fragment of anti aircraft shell.

tically is to be recommended. I foresee nothing likely to alter the indications for resection of the injured colon which I have ventured to promulgate on more than one occasion: (a) the cecum or colon is in a state of infarction; (b) there is extensive separation of the bowel from its mesocolon or vascular supply, especially if the mesocolon is also the site of a hematoma or is actively bleeding; (c) the vitality of the bowel is extinguished by a large piece of metal or other fragment hurled with the cyclopean force of modern high explosive; (d) the wound of the large intestine is of such magnitude, or the surgical approach to the part of the colon damaged is associated with such difficulty as to suggest the formation of an artificial anus as a surgical *pis aller*.

I only know of two successful exteriorization operations for injuries of the large bowel in this war.

In the traumatic colonic lesions of war it is preferable to complete the resection quickly by the form of anastomosis with which the operator is most familiar. The addition of a prophylactic or of a temporary intraperitoneal colostomy is a useful and perhaps life-saving expedient.

Multiple resections of bowel. Multiple resections of bowel were often successfully performed by surgeons before the last war for various pathological conditions unconnected with traumatism. During the war of 1914-1918 plunsegmental resections for injury aroused grave forebodings in the minds of operators, and various recommendations were made in order to obviate the necessity of removing more than one length of damaged intestine. Nevertheless, I had 11 successful cases of double resection, which represented a 50 per cent recovery rate in the patients submitted to this operation at my hands. No case of a successful triple resection for gunshot injury of the bowel was known to me in the last war, although W. A. Campbell had a triple resection with death from a chest complication when success appeared to be within his grasp. During the last 25 years successful multiple resections of intestine are of almost everyday occurrence, and I myself have had numberless cases of double and even of triple ablations. I recall the case of 1 patient who actually sur-

vived the removal of 7 segments of bowel for a complex and complicated carcinoma of the colon!

During the present War Meyrick Thomas has brilliantly and successfully performed a quadruple resection of small intestine damaged by a "tommy-gun" at close range.

T. L. was shot in the abdomen at short range, about 36 hours previous to admission to hospital. There was a small wound of entry about 1 inch below the umbilicus with about 1 inch of bleeding omentum protruding. At operation a part from several simple sutures of damaged gut, 4 resections of shredded length of ileum about 1 to 2 inches long were found necessary. End-to-end union was employed in each case. The distance separating the various anastomoses varied from 12 to 18 inches. Four wounds of the bladder were found, but the condition of the patient did not permit of anything more than a temporary suprapubic drain. He made a good recovery.

Protrusion of the abdominal viscera. Prolapse of the omentum has a diagnostic rather than a prognostic value; the prognosis depends upon the associated visceral damage rather than upon the fact of damage or extrusion of the omentum itself.

Hernia of the bowel resulting from enemy action varies from complete evisceration to the protrusion of one or two segments of intestine. Over 20 years ago cases with extrusion of gut were accounted bad surgical risks; nevertheless, Owen Richards, successful pioneer operation was performed upon a soldier with extruded and damaged intestine. Among others, the writer had several successful cases of suture or resection of prolapsed bowel. From the material now under review the recovery rate from operation for prolapsed and nonperforated small intestine is about 50 per cent, the mortality being mainly determined by concomitant damage, but when the small gut is not only extruded but also injured the mortality is about 80 per cent.

In cases of prolapse of the large bowel the prognosis is very grave, although several remarkable recoveries have been effected by skillful and courageous surgery. For example, Mr. F. J. S. Heaney successfully operated upon a man of 26 who was injured in the street by a bomb splinter. On his admission to hospital the large intestine extruding feces was found to be prolapsed through a large rent in

the left loin After resuscitation with 2 pints of plasma, he was operated upon 3 hours after admission

The wound was thoroughly excised, the damaged prolapsed descending colon was removed, and a side-to-side junction effected between the transverse and the pelvic colon The peritoneum was completely closed, but the posterior portion of the flank incision was left open A prophylactic temporary cecostomy was performed A fairly normal convalescence was established

In view of the grave prognosis which attends *prolapsed and damaged bowel*, the following cases are noteworthy

A patient (Mr O V Lloyd-Davies' case) was admitted to hospital with a huge lacerated wound of the lower right quadrant of the anterior abdominal wall, and most of his bowel lying in his trousers Shock was profound, but the man was conscious The usual methods of resuscitation were utilized, including a blood transfusion, the clothing was slit up, and the prolapsed bowel merely covered with a warm saline pack The abdomen and the extruded gut were covered with stone fragments, mud, mortar, etc., the 2 lacerations of the ileum were repaired by suture The wound in the abdominal wall was widely excised, the extent of tissue loss was now alarmingly evident, and much ingenuity was required to close the peritoneal and muscular gap The skill of the surgeon and the scientific postoperative measures contributed to the successful issue (a) Continuous stomach suction was continued until normal peristalsis was heard all over, and until there was no distention and the bowels were open normally (b) Continuous intravenous drip (1 bottle of normal saline in proportion to 4 bottles of isotonic glucose, if good cloud of urinary chlorides, glucose increased and vice versa) This was continued for 13 days As much as 15 pints per 24 hours had to be given at first to keep pace with the measured and estimated fluid loss Peristalsis gradually became normal, low pitched and present all over the abdomen, fluid was now passing through from the stomach, careful dosage of prostigmine, 1 cubic centimeter intravenously, and later small doses of Epsom salts started normal bowel action The wound was septic, but held together astonishingly Three months later the man was readmitted to hospital with signs of intestinal obstruction A straight x-ray picture showed numerous small gut fluid levels all over the abdomen At operation, numerous adhesions were found, most marked in connection with the lower small intestine and in the ileocecal region Multiple adhesions were divided, a small perforation occurred and was sutured After treatment was the same as before Recovery was complete and he is doing moderately heavy work, wearing a canvas belt

A member of a bomb disposal squad (Mr Geoffrey Parker's case) was standing in the open, about 10 yards away from the bomb, when it exploded His clothes were partly torn off, and his intestines were found "lying in the grass" On admission to hospital, he had a large wound in the right iliac fossa, about 4 inches diameter in all directions A field dressing somewhat inadequately covered the 3 feet of prolapsed ileum One loop of ileum had 2 large rents, almost completely dividing the bowel, the mesentery of this portion of the bowel was also damaged A limited resection of small gut was performed The parietal peritoneum was also extensively torn up, and blood had exposed the extraperitoneal aspect of the bladder, and had tracked through the femoral canal into the thigh and along the spermatic cord The blood was found to come from the horizontal ramus of the pubis, in which was impaled a small piece of bomb casing The man made a good recovery

Wounds of the duodenum The Spanish War confirmed the sinister reputation of wounds of the duodenum and pancreas which had been established in the great war of 1914-1918 The number of cases of injury to the duodenum at present available is too small for any reliable conclusions to be drawn as to the fatality of these wounds, it may be said, however, that successful operations have been performed for duodenal injuries in this present war (Rex Williams, Hedley Atkins, Henry R. Thompson and T J Cobbe)

Driver B (Mr Hedley Atkins' case) was wounded in the loin by a machine gun bullet while lying face downwards on the deck of one of H M Destroyers which was transporting him from Dunkirk to England The wound of entry was about half an inch in diameter and situated close to the spine, the track thence passed forwards and to the right between the first and second lumbar transverse processes When seen 4 hours after wounding, his general condition was good He had vomited once or twice, his upper abdomen was rigid, but peristaltic sounds were normal The wound in the loin was first dealt with, and next the abdomen was opened by a high right paramedian incision The peritoneal cavity was full of blood, there was a perforation of the anterior wall of the second part of the duodenum, and also on the posterior surface of the liver, from this latter blood was oozing freely The bullet had obviously skirted the medial border of the superior pole of the right kidney and had damaged both walls of the duodenum The wound of the anterior wall of the duodenum was sutured, the peritoneal cavity cleared of blood by suction, and the rent in the liver plugged with gauze Some discharge of duodenal contents took place from the wound in the loin, but this ceased after a few days and the man made a good recovery

Rare as are successful operations for duodenal injuries, Henry R. Thompson has actually two to his credit:

Jack S., a boy of 16, was hit in the street by a fragment of bomb. On admission to hospital, shock was severe, there was cyanosis of lips and cheeks. He complained of pain in the pit of the stomach, and had vomited once. There was retrograde amnesia. A puncture wound was present, centimeter in diameter and situated $1\frac{3}{4}$ inches internal to and just above the left anterior superior iliac spine. There was marked tenderness over the ascending colon and absence of intestinal sounds. There was a graze over the right costal margin and a small wound on the flexor aspect of the left forearm. At operation a perforation of the duodenum near the pyloroduodenal junction, as closed by suture and similar perforation of the anterior wall of the stomach was treated in a similar fashion. Despite subsequent right basal pneumonia the patient made good recovery. A fragment of metal was seen on x-ray examination to be still present in the right upper abdominal quadrant, probably in the liver.

The second man, sleeping in bed on his back when, as a result of near miss bomb was akened in the small hours of the morning by what appeared to be a severe blow on the abdomen. The injury may have been due to blast, or some fragment of the bomb may have hit his abdomen, although there was no bruise or abrasion to indicate such mechanism. On admission to hospital, the patient as in considerable abdominal pain, the pulse rate was 80, he was tender and rigid in the upper right abdominal quadrant. The man was kept under close observation, and after 3 hours, although there was no change in the pulse rate or in its volume, the tenderness and rigidity now involved the whole of the right side of the abdomen. Operation was performed 6 hours after the injury. A large subserous hematoma was found, which had spread over the duodenum from the pyloric end of the stomach and had infiltrated into the layers of the transverse mesocolon. The peritoneum over the duodenum was found to be ruptured at the junction of the first and second portions. The rupture of the bowel was not quite complete, about $\frac{1}{4}$ centimeter gut still was still intact. At the site of the tear the various coats of the bowel had been separated and stripped asunder, the prospects of satisfactory end-to-end junction seemed doubtful. Accordingly the duodenum was completely divided, the two ends were closed and posterior isoperistaltic gastrojejunostomy was performed. The man made a good recovery.

Surgeon Commander Rex Williams performed a successful operation in the case of a laceration of duodenum.

W. B. Bracey, aged 24, seaman, admitted from sea with penetrating wound of the right flank which resulted from an enemy bombing attack.

TABLE I.—RECOVERY RATE OF
INTESTINAL INJURIES

1 Series of the small intestine	
Total number undergoing operation for injuries including small intestine	733
Number of recoveries	
Percentage of recoveries	47.31
Number of operations for abdominal injury confined to small intestine	19
Number of recoveries	21
Percentage of recoveries	64
2 Series of the large intestine	
Total number undergoing operation for injuries confined to large intestine	63
Number of recoveries	63
Percentage of recoveries	40
Represents 45% of all operations for abdominal injuries	
Sir Cathbert Wallace reported 35% in 1918	
Sir Cathbert Wallace reported 37.5% in 1919	
Represent 27% of all operations for abdominal injuries	
Sir Cathbert Wallace reported 41% in 1920	

Severe shock was present and as promptly treated. After an interval of approximately 12 hours after the receipt of injury the abdomen was opened through a right upper paramedian incision. The second portion of the duodenum was found to be almost completely torn across, and there were also penetrating wounds of the proximal jejunum and transverse colon. The duodenum was sutured in its transverse axis and the other injuries repaired in similar fashion. A foreign body was found 10,000 units of Bacillus welchii serum were introduced into the peritoneal cavity and the abdomen closed with a drainage tube. Recovery was uneventful. When he was seen 2 months later he had returned to duty and barium meal investigation revealed no abnormality in the stomach, which was empty in 4½ hours. The duodenal cap filled well, appeared normal, and was not tender. A large metal fragment was seen in the abdomen lying posteriorly behind the pyloric portion of the stomach.

Yet another case of a wound of the duodenum successfully treated is that of Mr. T. J. Cobbe.

The patient, C. M. M., a mate, recovered from injuries due to fragment of bomb which not only damaged both walls of the stomach, but also wounded the duodenum and the colon.

Injuries of gall bladder and extrahepatic biliary tract. In this series there seems to be only 1 case of injury to the gall bladder. This was successfully dealt with by Miss E. M. Hall, F.R.C.S. There were multiple injuries including a penetrating wound of the abdomen, a perforated gall bladder and a ruptured liver were found at operation. The liver was sutured and the gall bladder was drained. There were

many other injuries affecting the skull, eyes, forearm, hand, etc., nevertheless, the patient recovered

Injury to biliary tract due to "blast" Kathleen T., aged 3 years, was the only survivor in a few houses which were completely destroyed by high explosives. She was the only living being when rescue parties arrived at the scene of the "incident." On admission to hospital she was in a state of severe shock. Apart from slight bruising of the right shoulder, there were no lacerations or external injuries. The abdomen was rigid and tender. After several hours the respirations became more rapid, and vomiting occurred. Operation was beyond consideration, a diagnosis of a ruptured diaphragm was tentatively put forward by me. After about 5 days the general condition slowly improved, the function of her bowel was restored, vomiting much less frequent. In 3 weeks' time the abdomen was becoming more and more distended in this lower portion, and its increasing size embarrassing both eating and movement. Twenty-five days after the "incident" the abdomen was opened under gas and oxygen, a large cystic swelling filling the whole abdomen was found, whose upper limit was not determined. Eight pints of bile-colored fluid were evacuated, and reported upon as consisting of "bile remnants." From this time her recovery was almost uneventful, and she is now well (Mr J. H. Buttery's case).

Injuries of the spleen The spleen has proved very vulnerable in this war, and has been damaged by penetrating injury, by subparietal crushes and by the effects of "blast." In such fatal nonpenetrating injuries from crushing mechanisms, burial, etc., as have come to autopsy, the spleen has been the organ most frequently damaged, when death has been solely or chiefly attributable to the abdominal lesion.

The recovery rate has been 55 per cent, which is a 10 per cent improvement on the figures of 1918.

Injuries of the appendix vermiformis In only 2 cases in this series collected from this war has there been any note of an injury to the appendix. In 1 case, the injury was inflicted by a revolver bullet, in addition, there were 4 wounds of the terminal ileum. The man recovered.

Injuries of the rectum In this present series, 52 per cent of patients with injuries of rectum have lived, an improvement on the 33 per cent recovery rate in the last great war (Sir Cuthbert Wallace). When the bladder is injured as well, 33 per cent recover.

Several cases have been observed of the explosive wound of the perineum, this seems to occur when the missile passes superficially across it. The sphincter surrounded by a circumanal ring of skin may be torn away from the surrounding skin, and may be drawn high up into the perineal tear. Mr W. B. Gabriel and Lieut. Col. Cameron MacLeod, R. A. M. C. have observed such a case in this war.

The value of the local employment of sulfanilamide powder in rectal injuries seems to have been clearly demonstrated in the successful case of a patient operated upon by Surgeon Commander Frank Stabler, R. N. V. R.

A Nazi officer in an E-boat was admitted to hospital with wounds in the back and buttocks from fragments of a shell from one of H. M. Destroyers. One of these splinters traversed the sacrum and damaged the underlying rectum. This posterior wound was excised, damaged fragments of sacrum were removed, and powdered sulfanilamide was insufflated in the track. Laparotomy was then performed, and a perforation of the rectosigmoid junction was sutured. A retroperitoneal hematoma was evacuated. No colostomy was performed. This type of case with bone injury, presacral blood extravasation and an associated large bowel injury did extremely badly in the last great war, the use of the sulfonamides marks a definite advance in the treatment of this type of case.

Injuries of bladder Penetrating wounds of the bladder have shown a recovery rate of only 35 per cent, which is rather lower than the 40 per cent of the last war (Sir Cuthbert Wallace). The recovery rate is approximately the same when the bladder is injured along with the rectum or colon.

The reminder to examine the interior of the bladder digitally, when there is perforation of that viscus, will often lead to the discovery of the missile. A bullet was even found lodged in the prostatic urethra (Major A. S. Till, R. A. M. C.).

Complicated abdominal injuries Multiple wounds of the abdominal viscera, especially the hollow viscera, manifestly render the prognosis of injuries to the belly more grave. The factor of serious concomitant hemorrhage makes the outlook still more serious.

A man was hit by a machine gun bullet. There was a small wound of entrance in left epigastrium over the left rectus at the level of the uppermost linea transversa, blood and air were bubbling out of this wound. Small wound of exit through left erector spinae, the level of which was about 1 inch lower than the en-

trance wound. This wound was very small, bled very little, and was situated just lateral to the transverse processes. Lesions found at laparotomy included (1) perforating wound of anterior surface of stomach, close to greater curvature with severe bleeding from this perforation, about $\frac{1}{2}$ inch in diameter; (2) posterior surface of stomach wound of exit into lesser sac with very little extravasation; (3) perforation anterior surface of terminal part of duodenum close to duodenojejunal junction there was severe bleeding from this wound; (4) perforation of posterior surface of duodenum, but comparatively little extravasation; (5) severe bleeding from transverse mesocolon (right colic vessels); (6) large bowel in condition of spasm, small bowel dilated and immobile. The case ended fatally.

Two wounded patients were admitted simultaneously to the same hospital, an old woman of 78 years and a girl of 3 years. Age perhaps did not play such an important part in determining the final ending, for in each case the injuries were of multiple or severe character. In the case of the old lady (Mr. H. R. S. Harley's case) there were present (1) laceration of upper and outer part of the right thigh involving the deep fascia; (2) compound fracture of the trochanteric region of the left femur with retained foreign body; (3) 6 lacerations of the buttock; (4) Pott's fracture of the left ankle; (5) laceration of scalp; (6) tender rigid abdomen in which autopsy revealed much blood, and large perforations of the jejunum. A retained fragment $\frac{1}{4}$ by $\frac{3}{8}$ inch was present.

The child of 3 years was admitted a quarter of hour after the incident in condition of extreme shock. A single wound covered with brick dust was present, and from it there protruded several feet of dust covered small intestine. After intensive resuscitation, the small intestine was washed and replaced inside the abdomen by Mr. Wase in an incredibly brief space of time. Despite every measure death ensued.

An officer at the termination of a parachute descent, landed in the fork of a tree, and received penetrating wound of the rectum, branch disrupting the pararectal tissues right up into the iliac fossa, the peritoneum was torn. The injured man then fell to the ground sustaining severe fracture of the pelvic girdle. There was a wide separation of the symphysis and disruption of the sacrospinous symphyseal ligaments. He survived his injuries about a year.

On the other hand some cases have made splendid recoveries.

R. H. R. male was injured by a splinter of bomb and sustained damage to stomach, transverse colon, and small intestine. There were also injuries to the right kidney, left leg, and left arm. The wounds of the stomach and small bowel were sutured. The colon was so severely damaged that a resection of a piece of the large bowel was necessary. Recovery (Case of Mrs. G. M. B. Toland F.R.C.S.)

C. R., male, aged 34 years, as admitted to hospital half hour after the incident. He is found to be suffering from the following injuries: (1) penetrating wound over the middle of the upper part of the right rectus abdominis. Examination of the abdomen demonstrated rigidity and generalized tenderness; (2) through-and-through wound of the middle of the left thigh with retained foreign body, but no bone injury; (3) penetrating wound of the left leg with a retained foreign body; (4) superficial laceration of the buttock. Operation took place 6½ hours after injury. Surgeons (Mr. Wase and Mr. Thomas) co-operated. Three pints of blood were found in the peritoneal cavity. There was a wound of the greater curvature of the stomach, near the pylorus, wound of the transverse colon and 7 wounds of the small bowel, from one of which a bomb fragment was removed. All these perforations were sutured. A rent on the inferior border of the liver which was not bleeding, was left alone. Recovery took place.

A sailor with almost every region of his body damaged, including his small intestine was successfully operated upon by Surgeon-Commander Frank Stabler R.N.V.R.

The man was hit by cannon shell 6 hours before admission to a naval hospital. He had the following injuries: (1) frontal region laceration with fracture of outer table of skull; (2) punctured wounds of abdomen above pubis, which had produced 6 perforations of jejunum about 1 foot from duodenojejunal flexure; (3) right hand, index and middle fingers blown off fifth metacarpal compound fracture and many penetrating wounds; (4) compound fracture of left olecranon; (5) 9 punctured wounds of left thigh; (6) punctured wound right thigh; (7) compound fracture of left patella. Seven inches of bowel were excised including 5 perforations; the sixth perforation was treated by separate suture. No drainage was employed in the space of 4 hours, pints of blood and plasma were given.

It is associated severe fracture especially a compound fracture loads the scales heavily against the victim with an abdominal injury—a smashed femur complicating a belly wound or contusion especially at its upper extremity is a burden hardly to be borne by suffering humanity.

Nevertheless, such patients have survived.

Mr. Kenneth Bond had under his care a bomb injury admitted with small opening close to the anus which led into large cavity on the right side of the rectum and involved complete division of all the splinters including the anorectal ring. The man had also sustained multiple fractures of the anterior portion of the pelvic ring, and an incomplete rupture of the urethra. Finally double spiral

fracture of the right femur completed the list of his injuries. The end-result consisted in a complete recovery of function of all the systems involved.

A patient of Mr F G Wrigley actually survived an *injury to the abdomen and a compound fracture of both femora*.

This patient (Mr F G Wrigley's case) received a bomb injury to abdomen, with contusion of colon, damage to omentum, extensive extraperitoneal wound of lower left iliac region, bilateral compound fracture of femur, wounds of right forearm, and right temporal region. She recovered from the abdominal injury, although a fecal fistula formed 4 months later. She ultimately succumbed from mental deterioration and the effects of sepsis in connection with one of the wounds of the thigh.

In a patient who was under the care of Mr A L Candler, after she had received a *penetrating wound of the abdomen and a fracture of the right femur*, a completely successful result was obtained.

This occurred in a woman of 30 who was putting out incendiaries on the night of an intense raid on a city. On admission to hospital, shock was extreme. After measures for resuscitation had been employed, laparotomy was performed, and several intestinal perforations sutured. The hospital was badly damaged the night following, and the woman was transferred to an infirmary in another town, her pulse was 120 after her transportation. Her subsequent course was punctuated by several alarming or disquieting incidents, large quantities of pus and blood were passed by the rectum, and a transfusion of 3 pints of blood on one occasion was required. A few days after this a small intestine fistula appeared at the bottom of an unhealthy-looking abdominal wound. This finally healed, the patient making a complete recovery.

An unusual mode of wounding was noted in the case of R A C who was blown by the blast wave from a detonating bomb on to the roof of the car beside which he was standing. Then came a second bomb, from which he received 16 superficial splinter wounds of the left lower limb, but also a penetrating injury of the belly. No visceral injury was discovered on laparotomy. The man recovered.

It is possible for those persons who are *maimed by high explosive*, in addition, to *suffer from burns*.

H W W, male, aged 46 years, was extinguishing an incendiary bomb with sand when it exploded. He received burns of the face and hands, and 4 punctured wounds of the abdomen. At operation, 1 large and 1 small wound of the ileum were sutured, as well as a small tear of the transverse colon. He recovered.

ABDOMINOTHORACIC INJURIES

Uninformed lay opinion is prone to associate penetrating injuries of the trunk with a dire mortality, and statistical inquiry only too truly confirms the fatality of wounds involving certain lethal anatomical areas, and the severity or serious consequence of many wounds of the less mortal regions of the thoracico-abdominal zone under conditions of modern warfare. The behavior of wounds of the diaphragm itself had been known to surgeons since the days of Ambroise Paré, and was accurately noted and discussed by Guthrie when writing of the war surgery of the Napoleonic era. The operative treatment of thoracic wounds by Guthrie and by Baron Larrey, Napoleon's great Surgeon General, anticipated, though in immature fashion, the modern treatment of wounds of the chest received under conditions of war. The early story of the abdominal aspect of the problem has already been told.

Injuries which involve thorax, diaphragm, and abdomen may be of penetrating or of non-penetrating character. In the war of 1914-1918, the first named group completely overshadowed and outnumbered those which were subparietal lesions, in this present conflict the cases for which surgery is possible still belong almost exclusively to the former class.

Penetrating injuries. In one series of cases from the war of 1914-1918 (Sir Cuthbert Wallace, 1922) abdominothoracic cases constituted 12 per cent of the abdominal cases which reached the casualty hospitals of one army, the operations performed on this group of patients also accounted for 12 per cent of all the abdominal operations in that army. In the Spanish Civil War the percentage of the bellies admitted to a hospital of first urgency was not dissimilar to that which obtained in 1914-1918, i.e., 11 per cent (Jolly, 1940). Abdominothoracic injuries in the present series of abdominal injuries from this war approximate 13 per cent, the ratio is therefore not dissimilar to those of previous campaigns.

Statistics of abdominothoracic wounds culled from the official history of the war of 1914-1918 demonstrate that in a vast majority the abdominal lesion determines the gravity of the prognosis, and, further, that wounding of the

hollow abdominal viscera greatly augments the fatality of the injury. It will at once be apparent that the anxieties occasioned by a wound of the left dome of the diaphragm must greatly exceed those which are aroused by right-sided penetration of the midriff. An analysis of cases from this war confirms the truth of both these statements.

Of 78 abdominothoracic injuries in this present series 42 were right-sided and 36 were left-sided. Forty nine patients survived, i.e., a recovery rate of 63 per cent, a figure which very nearly equals that attained by 6 surgeons of the Fourth Army in 1918 during the last great war. In this present series 70 per cent of the patients with right-sided abdominothoracic wounds lived whereas only 50 per cent of the left-sided abdominothoracic patients survived.

An excellent classification of penetrating abdominothoracic wounds has been given by my friend Tudor Edwards

- 1 The chest and abdomen may be penetrated by separate missiles, the wounded man sometimes becoming a veritable St. Sebastian, his abdomen and chest riddled with fragments of high explosive or machine gun bullets.

- 2 Missiles may penetrate the chest and may emerge through the abdominal wall or be retained within the belly on the other hand, the track of the missile may be in the reverse direction—the wound of entry in the abdomen and the fragment retained within the thorax.

- 3 Traversing wounds of the lower chest, especially if inflicted during expiration may pass through the diaphragm and occasion damage to the abdominal organs lying immediately subjacent to the midriff

- 4 Tangential wounds of the lower thorax in which considerable damage, including diaphragmatic injury and perforation is produced by the missile and in-driven fractured ribs.

The diaphragmatic lesion. The present war series confirms many of the findings of a quarter of a century ago. The injuries of the diaphragm in abdominothoracic lesions are still mostly found in the sloping muscular portion and are especially frequent when this lies in contact with the thoracic wall. In cases that come to operation the rent is usually small. In one series the linear tear was half an inch long

or less in 50 per cent of the cases. Many openings are mere punctures. Larger irregular apertures in those suitable for surgery are seldom found to be more than $1\frac{1}{2}$ to 2 inches in diameter.

Lockwood and Niton (1918) compared the cardiac and respiratory embarrassment due to a rent in the diaphragm to that produced by an open pneumothorax on the other hand for Sauerbruch the importance of the diaphragm in relation to respiration and the circulation was exaggerated. The great improvement in the recovery rate of abdominothoracic cases after the diaphragm began to be sutured by British surgeons in the last war may have been partly due to the repair of that muscle but also to the improved treatment of the thoracic condition and increasing familiarity with the many problems of war surgery. Small wounds undoubtedly heal spontaneously and others are at least temporarily plugged by omentum, spleen, liver stomach, etc.

Wounds of the central tendinous part are obviously more serious than those at the periphery but some have survived. A century ago Guthrie published notes of a man with a wound of pericardium left ventricle lung liver and the tendon of the diaphragm. The man survived for 4 or 5 months he suffered from palpitation and uneasy sensations in the chest, and died of bronchitis. Fuchs (Sauerbruch and O'Shaughnessy 1937) successfully operated upon a patient with a stab wound of the right ventricle which also perforated the central portion of the diaphragm. The track passed obliquely inwards from the fifth sternochondral articulation and was thought before operation to implicate the stomach.

Diagnosis of penetrating abdominothoracic wounds. Doubt may sometimes be felt at first whether the gravity of the condition of a man with an abdominothoracic wound is due to the thoracic, to the abdominal or to other concomitant injury. Nixon (1919) who had great experience of these cases thought that if there is a fair air entry into the lungs thoracic injury is not to be held accountable.

The anatomical site of the aperture of entry and of exit in a traversing wound of the trunk limits the track of the missile with fair accuracy. The position of the patient at the time of

injury also demands consideration, the structures probably damaged may then be readily adumbrated. In cases in which a fragment of metal, spicules of broken rib, etc., are retained, radiological investigation is indispensable, its necessity in estimating diaphragmatic movements and thoracic pathology cannot be overestimated. There are also clinical signs and symptoms which arrest attention and which may clarify, or may, on the other hand, obscure, the diagnosis.

1 Abdominal rigidity does not of necessity betoken involvement of the subphrenic viscera. It is well known that injuries of the pleura or lung, especially if situated in proximity to the diaphragm, may occasion abdominal rigidity and may arouse suspicion of an abdominal lesion.

2 Sickness and vomiting have been known to occur in cases of lower thoracic injury, but are more frequent in abdominal lesions, as is eructation of gas.

Diaphragmatic injury is suggested by an almost entirely thoracic type of respiration, with a catch at the end of inspiration, sometimes a definite spasm or hiccup, yet the actual respiratory rate may be little altered. In the late stages of injury to the diaphragm there is fixed pain, exaggerated on exertion and referred to clavicle or scapula according to the position of the injury or location of the retained missile. Pain is induced especially by lifting, coughing, or even deep respiration. The diaphragm is kept motionless on the affected side.

The diagnosis of a wound of the diaphragm is not easy in subparietal injuries. The syndrome of tension pneumothorax may be simulated by the sudden irruption of stomach or colon into the chest. Radiology and the determination of the intrapleural pressure enable a correct diagnosis to be attained.

The existence of *blast contusion of the lung* is now well established on clinical and x-ray evidence and by postmortem findings, and the dangers attending the use of inhalation anaesthesia in these cases are overwhelming, great caution must therefore be employed when this is suspected, yet blast contusion of the lung is sometimes only the index of perhaps graver changes in the organs below the diaphragm.

Other serious cases may have been in very close proximity to detonating bombs, and may be suffering from a dangerous and grave degree of saturation of the blood by explosive gases, such as carbon monoxide or nitric oxide. The severity of the clinical state may even be due to such lesions as myocardial trauma. Such possibilities should not be overlooked amid the circumstances of this "total" war, their presence and the existence of other grave multiple injuries heavily load the scales against recovery.

Penetrating injuries by large missiles. The injuries produced inside the chest or abdomen by large fragments of metal or other foreign body are almost always irrecoverable, the result is scarcely likely to be different in those wounds if more than one cavity of the body is implicated. There was in the Royal College of Surgeons' Museum till the time of its destruction a piece of brass tubing, $4\frac{3}{8}$ inches long, removed by Mr. Reginald Vick in Macedonia from a Greek soldier, who recovered after the simple extraction of the missile, which had passed from the middle of the right scapula and projected in the epigastrium (Gordon-Taylor, 1939).

Saint (quoted by Gordon-Taylor) had a successful right-sided abdominothoracic case in which a fragment of shell weighing 2 ounces had traversed chest, diaphragm, and liver and produced 2 perforations of the duodenum and 1 in the hepatic flexure of the colon.

In one of my patients, the successful result of whose case is recorded elsewhere, a missile weighing nearly 4 ounces produced the most grievous damage inside the belly and fractured the bony wall of the thorax (Gordon-Taylor, 1919), the diaphragm was apparently uninjured. In the penetrating abdominothoracic wounds which form a section of the series collected from this war, there is no record of any case that controverts the reputed fatality of the large missile when it wounds the trunk.

Treatment of penetrating abdominothoracic injuries. This contribution is largely concerned with the surgical treatment of injuries of the diaphragm and of those abdominal organs whose anatomical proximity renders them specially vulnerable in cases of diaphragmatic wounding.

Treatment of wounds implicating the liver
The dimensions and the velocity of the missile play an important part in determining the type of hepatic lesion, which may be almost protean in character. Large fragments of liver may be torn off, and as much as one third of the right lobe has been found loose in the peritoneal cavity of a patient who recovered from a right-sided penetrating abdomino-thoracic injury in the last war.

Before their total destruction the specimens in the Royal College of Surgeons War collection illustrating gunshot wounds of the liver revealed many lesions for which any surgery must be futile or incomplete: thus it would be impossible by operative measures alone to prevent infection throughout the length of a ragged track running from the right lateral surface of the organ to its extreme pole on the other side of the body. In many cases of liver injury due to enemy action there are few arresting clinical signs, and it is significant that out of all the penetrating injuries of the abdomen which recovered in the last war without operation the wounds were mostly situated in the liver area. Surgical intervention directed towards the liver is indicated under the following circumstances only: (1) gross hemorrhage from the liver which mainly depends on whether large veins in the organ have been injured—hemorrhage otherwise ceases spontaneously as does oozing of bile unless main ducts are severed; (2) the association of some thoracic or another abdominal lesion demanding exploration; (3) the retention of a missile in the liver especially a large missile in an accessible position in that organ. In the case of severe laceration of the liver packing may be necessary to control hemorrhage. In some such patients the diaphragm may be sutured, and the thorax closed in the approved manner with airtight drainage of the pleura by means of a Malecot's tube inserted through a separate intercostal incision. The gauze pack is brought out through another separate incision in the anterior abdominal wall. In other cases the diaphragmatic opening may be enlarged parallel with fibers from mediastinal to lateral border: the diaphragmatic edges are now approximated to the intercostal muscles and the pleura is thus shut off from the drainage track.

Early jaundice in cases of hepatic injury may be present, and is usually slight and evanescent: the possibility of a collection of bile in peritoneum or pelvis should always be considered. Late jaundice has a much graver significance, and indicates serious infection.

Secondary hepatic hemorrhage in penetrating abdomino-thoracic injuries is almost always fatal, and is usually associated with signs of sepsis such as pain, elevation of temperature and pulse rate, abdominal pallor, restlessness and loss of strength.

The formation of an intrahepatic abscess round a retained fragment may be dealt with successfully by surgical measures.

Treatment of gunshot injury of the spleen. A study of the specimens of gunshot injury of the spleen in the war collection formerly housed in the Royal College of Surgeons used to suggest that wounds of that organ are frequently complicated by damage to adjacent viscera; yet in some collected clinical series it is stated that in more than half the cases of splenic injury revealed at operation there was no damage to other abdominal organs. This was certainly not my experience (Gordon Taylor 1930) which is in agreement with that of Major Jolly in his surgical work with the Spanish Republican Army (Jolly 1940).

The propriety of primary splenectomy in cases of gunshot injury still remains a subject of controversy. The removal of the organ should certainly not be resorted to lightly, heartedly, but in my opinion the procedure has not greatly increased the risk. The suture of the spleen may not be difficult when the organ is approached through the chest and diaphragm, but when explored by other routes cobbling of the organ is wasteful of time and may leave a sense of insecurity. Jolly (1940) and some of the Spanish surgeons write enthusiastically of splenectomy.

Numerous cases of successful transdiaphragmatic splenectomy in left-sided abdomino-thoracic wounds were recorded in the war of 1914-1918, some of which were associated with the operative repair of injuries to the stomach (Richard Charles, George Gask, J. E. H. Roberts, A. L. Lockwood, Gordon Bryan, Gordon-Taylor etc. and very recently by Valentine Logue). In the last war recovery has even

taken place in cases of left-sided abdomino-thoracic wounds in which left-sided nephrectomy as well as splenectomy had to be performed for complete disruption of each organ (Gordon-Taylor) and also in the present conflict (J Scholefield)

Treatment of wounds of the pancreas These injuries were less frequent in the war of 1914-1918, or at any rate were less often recognized, than injuries of any other of the abdominal viscera, it is not otherwise today. The intimate anatomical relation of the gland to the large blood vessels doubtless explains the paucity of wounds coming under the observation of the casualty hospital surgeons, doubtless some are unrecognized and are designated retroperitoneal hematomas. I have knowledge of only 3 abdominothoracic injuries implicating the pancreas in which recovery took place in the last war (Saint, Alan Curry, Gordon-Bryan), there are none in the present series from this conflict.

Treatment of injury to the kidney Each kidney is equally liable to damage. It was estimated that in 40 per cent of gunshot wounds of the kidney investigated at an English surgical base in France during 1914-1918 the thorax was also implicated. The propriety of immediate operation on the kidney in abdomino-thoracic wounds demands even more careful consideration than in purely abdominal injuries. Probably the best course is to excise the wound leading down to the damaged kidney, the organ can then be inspected and any foreign body removed.

In the majority of cases the renal injury plays a minor part in menacing life, and only for severe hemorrhage, a hopelessly pulped organ, or gross damage to the renal pedicle is primary nephrectomy indicated. In about 20 per cent of cases of gunshot injury of the kidney in the last war, life was threatened by secondary hemorrhage, consequent on sepsis, a retained missile, or an infarct of the kidney produced by damage to some branch of the renal artery, secondary hemorrhage is an infrequent phenomenon today.

Treatment of injury to the hollow organs Of hollow organs the stomach and splenic flexure of the colon are those most liable to injury, in suitable cases transdiaphragmatic laparotomy

affords excellent access to these organs. Concomitant involvement of the small intestine denotes a more vertical track of the missile, and demands a separate approach or a much extended incision, such a measure, though necessary, increases risk to life. Multivisceral damage also augments mortality, and vertical wounds, which may even extend from supra-clavicular fossa to femur, tend to be very fatal.

The possibility of injury to the duodenum must always be borne in mind, and any hematoma in its vicinity should be suspect, lest a retroperitoneal rupture of this fixed part of the small gut be overlooked. Every abdomino-thoracic case in the present series associated with a laceration of the hepatic flexure has perished.

Summary of treatment The treatment of penetrating abdominothoracic injuries may be summarized as follows

1 In many traversing (through-and-through) abdominothoracic wounds of the right side produced by a small bomb fragment or bullet *no immediate active surgical treatment* is required, provided that (a) no gross damage has been inflicted upon the thoracic or abdominal wall—fractured ribs, explosive effect, etc., (b) the direction of the track of the missile does not appear to compromise the general peritoneal cavity or suggest the desirability of its exploration, (c) the signs of abdominal hemorrhage or of injury to a hollow viscus are clearly absent.

2 In cases of right-sided abdominothoracic wounds in which a small fragment is retained in an inaccessible position in the substance of the liver an *expectant line of treatment* is the correct procedure, accessible fragments, unless small, should be sought and removed.

3 When there is an open, blowing thoracic wound or an associated "stove-in chest," the chest injury must of course assume chronological priority of treatment.

4 If the position of the wound of entry and exit in a left-sided abdominothoracic wound adumbrates a track implicating that fatal left subphrenic area of the abdomen, or if a radiograph demonstrates a fragment of metal retained in this region, the thorax should be dealt with first and access to the upper abdomen obtained through the diaphragm.

Fig 3 Room 5 which contained the majority of the comparative anatomy specimens belonging to the Museum which started with the original Hunterian collection

Fig 4 This shows amid the debris of Room 4 the bust of the naturalist, Owen, a former conservator, which was only partially damaged

5 When the thoracic injury appears insignificant, but there is evidence of severe widespread intraperitoneal damage especially in involvement of hollow viscera, the abdomen should be explored through an appropriately placed laparotomy incision. This instruction applies to wounds of thorax and abdomen produced by the same or by separate missiles.

6 When the thoracic injury seems slight, and when the evidence of a radiograph or the direction of a missile track in a through-and-through wound suggests an extraperitoneal course of a small fragment such an abdomino-thoracic injury may often be left alone.

If in such cases there is evidence of injury to the kidney, the parietal wound down to the kidney should be excised, the organ investigated, and any foreign body removed.

7 In cases in which the thoracic wound is situated low down on the lateral or antero-lateral aspect of the chest access to both supra-diaphragmatic and infradiaphragmatic areas may be obtained by cutting through the costal arch after the manner of Bland Sutton, Duval, Bérard, etc. this method of access is undoubtedly severe.

8. If an abdominothoracic injury has been approached from the abdominal aspect it is important not to waste time trying to complete a difficult suture of the diaphragm in a critically ill patient, *unless* the aperture in the midriff is so large that immediate or early herniation of the abdominal contents is certain to occur.

Nonpenetrating abdominothoracic injuries. There are no successful operations for sub-parietal abdominothoracic injuries indisputably involving the diaphragm in this present series of cases. The inference is that these cases involve such desperate or multiple injuries that death ensues; some such cases are found at autopsy. The experience of this war so far goes to show that abdominothoracic injuries due to fragments of high explosive or bullets are far less grave than those due to crushing force or the effect of blast.

A man of 5 years was admitted to hospital after having been dug out from under the debris of a house. He showed no marks of external injury, complained of no pain, distress, and as only slight bleeding. On the following morning he was dyspnoeic

and complained of pain in the left chest, there was tympany increasing during the day. On examination he was tympanic over the left chest up to the third rib, normal over the right. On palpation the left heart was displaced to the right. A ray suggested diagnosis of collapse of the left lung, pneumothorax and a pleural effusion. Just above the fluid level were some vague shadows which were thought possibly to indicate the presence of the thorax of gut. However on the supposition that the condition was tension pneumothorax, a needle was inserted in fourth intercostal space anteriorly and about 1 liter of air was let out with great relief to the patient. The process was repeated, and the needle was connected with receiver by means of rubber drainage. Fluids taken by the mouth escaped through the needle in the thorax. The patient was finally operated upon and tears in the diaphragm found, through which an enormous hernia of the stomach had taken place. Death occurred.

Mention has already been made of the advancement of the science and craft of surgery through the stimulus of war. The familiarity with the transdiaphragmatic approach to the vault of the abdominal cavity attained in the latter years of the war of 1914-1918 has been turned to useful purpose by thoracic surgeons since the war. The advances in this field are stupendous. Diaphragmatic hernia, especially that produced by injury is nowadays approached by the thoracic route in Britain. The operation of cardio-omentopexy gave good results in the late Mr. O'Shaughnessy's capable hands, and improvements in the technique of the operation have been effected by Mr. John B. Hunter. The general surgeon also avails himself of a thoracic approach in the operation for the surgical removal of the lower end of the esophagus or of the cardiac end of the stomach.

Increasing familiarity with thoracic surgery doubtless provided the stimulus for Pierre Duval's successful operation for the extraction of a bullet from the suprahepatic portion of the inferior vena cava, the sternum was split, and the diaphragm divided backwards to the caval opening in the midriff. To my mind this still remains the most brilliant operation in the history of surgery.

CONCLUSIONS

1. Despite the gravity of the wounds and the frequent association of multiple injuries, approximately 50 per cent of the patients with

abdominal injury for whom operation is possible survive

2 The military situation permits of no information as to the percentage of all abdominal casualties for which operation is possible

3 The percentage of recoveries for injuries to the stomach, the small intestine, and the spleen is actually higher than in 1914-1918, though the recovery rate for the large bowel is the same

4 Few patients have survived after lengthy resections of bowel

5 The employment of the sulfonamide locally and by oral administration has proved of inestimable value

6 The transfusion of blood or the blood derivatives has been employed on a liberal scale and this method of treatment has made a host of patients operable who would otherwise certainly have died

THE CARE OF THE LIGHTLY WOUNDED

WILLIAM DARRACH, M.D. Sc.D. LL.D., New York, New York

THE main thesis of my remarks is that far too little attention was paid in the last war to the care of the lightly wounded. By lightly wounded I mean wounds which do not involve any of the body cavities, such as the head, chest, or abdomen or any bone, major blood vessel or nerve. Most of these patients were ambulatory and, had they received prompt surgical attention, should have been able to return to duty within a few weeks. As a group they represented a considerable majority of all the wounded.

We were told that the main duty of the Medical Corps was to maintain the strength of the fighting forces yet the primary attention as well as the large majority of the time and effort of the surgeons was directed to the care of the severely wounded, very few of whom ever went back to duty. The lightly wounded "waited for the second table and got the leftovers." This was quite in keeping with our peace time training and humanitarian desires. If our main object is to save life those dangerously wounded should come first but if our main object is to win the war and maintain the fighting forces it would seem that the men who might go back to duty should receive at least equal attention and that the attempt should be made to reduce their period of disability to the minimum.

As I am expressing a purely personal and individual opinion I may be allowed to recount the experiences on which that opinion is based limited though they were. Going over with the Presbyterian Hospital Unit in May 1917 we were assigned to the British Expeditionary Force and No. 1 General Hospital at Etretat near Havre was turned over to our care. At the time of our arrival in France things had been relatively quiet for some time and most of the patients then in the hospital had been

sent down from the front area several weeks before. The main problem seemed to be to get the severely wounded patients well enough to be sent across the channel to England. These included patients with badly infected compound fractures, chest wounds, and a few who survived after abdominal injury. Also there was a large number of ambulatory patients with small infected wounds, many of whom had been under treatment for weeks and even months. In addition to their local wounds they had become soft and flabby and their morale very low. When their wounds finally healed they were sent to convalescent camps for more weeks of rehabilitation before going back to the rest areas to rejoin their divisions. When a train load of 300 to 700 new patients arrived at the base all hands concentrated on the severely wounded and those patients with minor injuries waited until all the others had been cured for. As the wounds by that time were 3 to 10 days old, not much was done except daily dressings by the junior medical officers or more usually the nurses.

After the Somme the British Expeditionary Force realized that the wounded could be handled better if their operative treatment was carried out nearer the front lines. In preparation for the battle of Passchendaele in July 1917 operating teams were sent from the base hospitals to the casualty clearing stations which were stationed 5 to 10 miles behind the lines and usually at a railroad. The patients came from the field hospitals to the casualty clearing station by ambulance and from there were sent down by train. They usually reached the hospitals 4 to 12 hours after injury. These hospitals were entirely housed in tents except for a Nissen hut for the operating theater. When we arrived on July 23 1917 there were 3 groups of these hospitals back of Ypres with 3 or 4 hospitals in each group. We were assigned to No. 47 Casualty Clearing Station with 7 other surgical teams. Each team consisted of a surgeon, an anesthetist, a nurse and an orderly. The duties of the

Presented before the Clinical Congress of the American College of Surgeons, Boston, November 3-7 1941.

operating team were twofold, to serve in the admitting ward and in the operating theater. In the former, wounds were merely inspected, dressings changed, and the decision made as to whether the patient should go to the resuscitation ward, preoperative ward, or be held for evacuation on the next train. When a rush was on, the admitting and sorting was done by one of the other medical officers. The operating teams were on duty 16 hours out of the 24 so there were 6 teams operating from 8 a m to midnight, and 4 from midnight to 8 a m. The plan in our group was for the ambulances to bring all patients to one hospital until 200 had been admitted, the stream then being diverted to the second hospital. By the time the third had admitted its quota, the first hospital was supposed to have finished with its group and be ready for the next. During a push, of course, the numbers were far greater than in the intervening times. During a lull it might take 24 hours to get our quota of 200 but on the second day of the first push we rotated 6 times, each hospital getting over 1200 patients. The worst cases, except for those patients obviously moribund, were operated on first. One severe case an hour was about the average that one team could handle. This meant that during the busiest period only 10 per cent of the patients received could be handled in the operating theater. The rest had to be sent on to get their operative care later on, perhaps the next day, perhaps a week later. This failure to give the lightly wounded early operative treatment was a necessity during rush times but the peak load necessity seemed to establish the general policy at all times, and general policies in the British Expeditionary Force or any army are hard to change. This I discovered during one quiet period when only 2 teams were on call. I took my team to the receiving tent and under gas operated on some of the patients with minor wounds who, as I had seen at the base hospital, required months to get back to duty. If operated upon early I thought they might recover within a few weeks. We were able to care for quite a few cases in a short time. Soon word came from the Commanding Officer "Sorry, but that's not done in the B E F." This same general plan seemed to hold in

other casualty clearing stations in our area. The French had already established the wisdom of early surgical treatment of minor wounds and during quiet times were doing a good deal of it in their advance hospitals. Coming back to the base hospital, I was again impressed with the long delay in healing of those minor wounds whose only early treatment was dressings, or occasionally some bipp paste.

After 14 months with the British I was transferred to the American Expeditionary Forces in the latter days of the battle of Château-Thierry. During this and the St Mihiel drive the problem was to meet the actual necessities with the materials at hand, but later in the Argonne, with more hospitals and better organization, the problem of providing the wounded with early surgical treatment was well met. In addition to a goodly number of evacuation hospitals, well equipped and with surgeons of experience, several mobile hospitals, notably Nos 1, 2, and 4, were set up sufficiently far forward to give the severely wounded an excellent chance for recovery. Yet here again, in both evacuation and mobile hospitals the major emphasis was placed on giving the severely wounded the right of way. The others were either attended to after the severe cases were finished, or were immediately sent down the line. In a few places operating teams were assigned to the lightly wounded group. Sherbondy and George Davis by using 3 tables, orderlies, and nurses proved that they could handle 6 to 8 cases an hour. At the time of the Armistice, Colonel Grissinger of the First Corps had plans all ready for execution for a special hospital well forward for the lightly wounded patients only, but it was never opened.

That early operative treatment of minor wounds will shorten tremendously the period of disability was proved at the hospital for the Army of Occupation in Coblenz. In the first month we had 83 cases of gunshot wounds all due to careless handling of firearms. This led one old regular to say "I always claimed that a soldier was the last person in the world to be trusted with firearms."

I have a vivid memory of a dressing station along the road that ran north from Ypres

along the canal. Here in a small cellar an attempt was being made to revive a patient with a badly shattered thigh and a perforating belly while huddled up behind what was left of the front wall of the house was a group of walking wounded waiting for transportation. Again at the field ambulance tired men were working over a row of stretchers, while near by a large group of walkers squatted down or curled up on the ground waiting for transportation. Near by was the narrow gauge railroad with its cars of shells coming up, and the cars going back—empty. Lorries were going up the road full of supplies of one sort or another and others going back—empty yet the walking wounded waited for ambulances. Again at the casualty clearing station when the ambulances arrived—patients on stretchers were cared for first while the walkers waited. Their dressings were changed, they were fed and herded to one side to await transportation by the next train to go down. I can see them when the train arrived at the base. Again the stretchers came first in the ambulances, while the walkers, who could slowly plodded the half mile from the railway station to the hospital. It sometimes took 24 to 48 hours of operative work to care for the severely wounded before the others could have their turn. It was too late then for any preventive work and for early healing. One found just dirty granulating wounds, often with insufficient drainage. Then came the long, slow weeks of healing with a gradual softening—physical mental and spiritual. This was the forgotten man.

In the Argonne the picture was similar. In the divisional triage as the stream of wounded men came in they were sorted out and passed down to the mobile and evacuation hospitals. Again the major attention and time were given to the severely wounded while the lightly wounded received either delayed treatment or were sent directly on with a mere change of dressing. These were the men however who if they could have had operative treatment early might have rejoined their units within a few weeks. Of the patients with severe injuries of the head, chest, belly or with compound fractures and tight calves very very few ever resumed active duty.

So much for the past. Can we profit by that experience in planning for the days that lie ahead? In times of retreat and especially the conditions the British faced in the days preceding Dunkirk little can be planned or carried out. The main problem is to get the wounded away at all. Any operative treatment must be delayed until they have been brought a long way to the rear. In stationary warfare or in times of an advance hospital facilities can be brought reasonably close, and operative treatment carried out early.

The surgical care of the lightly wounded varies from that of the more serious cases in several ways. Many of the latter patients need attention before they come to the operating table hence the need for resuscitation wards for combatting shock. Such a measure is unnecessary for the lightly wounded. In the operating room there are three periods first, the preparation of the patient and the induction of anesthesia, second, the operation itself and third the application of dressings and splints when necessary. In cases of major wounds the operation will require 60 to 90 per cent of the total time. One operator can use 2 tables at the most, the next patient being prepared as he operates and the last stage of operation being carried out by an assistant as the operator starts anew. With the minor wounds the time of operating may not be greater than that required for preparation and may be even less. One surgeon could handle 3 or possibly 4 tables with the appropriate number of assistants. While 1 serious case an hour can be used as a general figure for what one surgeon could handle with proper assistants he could operate on 6 to 8 minor cases.

After operation the serious cases will need a good deal of careful attention for hours and even days. The organization of postoperative wards and personnel is quite different from that needed for the late care of the minor wounds. Many of the patients with serious injuries are actually nontransportable for days and will do much better if they are not moved for a much longer period. Most of the patients with minor injuries could be transported within a few hours or a few days at most. Therefore is it not worth considering to arrange for entirely separate units to handle these 2

groups of cases? Each unit should be planned and organized according to the needs of the group assigned to it. As the stream of wounded starts back the two groups should be separated early. A large majority of the lightly wounded might be transported back in the supply trucks on their return journeys, the ambulances being used for the serious cases. Certain hospitals should be designated and planned only for the care of patients with minor injuries. Such hospitals should plan for a routine somewhat as follows. On arrival the patients would be examined by an experienced surgeon to pick out those sent by mistake who belong in the more serious group, and mechanism provided for their immediate transfer. The suitable cases then would go to the x-ray department for localization of foreign bodies. After this they would go to the preoperative ward for removal of clothing and rest until the operating theater was ready for them. In the operating room each surgeon would have 3 tables at his disposal and 3 teams. The patient would be placed on the first table, the first team preparing the field and giving the anesthetic. The same team would repeat this performance on the second and third tables. The surgeon and his assistant would follow after and débride the wound, treating by primary suture or packing with or without the use of chemotherapy and dictating orders for later care. The third team would then take over, apply the dressing, bandages, and any necessary splint. The patient would then be taken to the postoperative ward. If the lighter forms of anesthesia were to be used, either inhalation or intravenous, immediate after-care of these patients would be much simpler

than that of the more serious cases and would require a smaller personnel in these wards. With the exception of some of the lower extremity cases most of these patients would become ambulatory in a short period of time. This would simplify the feeding problem. At the time of operation the surgeon should be able to make a fair guess as to whether the patient should be retained or early returned to his unit or sent farther back for prolonged treatment. Final decision, of course, would have to be checked before discharge. This plan seems reasonable to me. In this way this "forgotten man" might be remembered and his minor wound prove to be a minor affair and not a cause of months of disability.

Many of us believe that the only kind of war casualties we will have to face in the near future, outside of the Navy, will be those resulting from bombs. Looking after the wounded civilian population may not be maintaining the fighting forces in the field and it may not be the duty of the Army Medical Corps, but it will have to be done. As plans are made to meet this emergency let us hope that such plans will include prompt attention to this group of lightly wounded. I was delighted to hear from a member of our staff who is now working in London that separate units have been established for this very purpose.

CONCLUSION

I feel strongly that the care of the lightly wounded as I saw it in France was greatly neglected. I sincerely hope that this will not occur when we have to meet the problem again. God grant that we do not have to, but should it come let us be ready for it.

and increases the intrapericardial pressure if denied free egress. Compression of the great veins at the base of the heart backs up the venous inflow and compensatory increase in venous pressure results. The blood pressure falls and the systolic and diastolic pressures tend to approximate each other because the heart is handling less blood. When the increasing venous pressure cannot overcome the intrapericardial pressure, circulatory arrest occurs. As little as 200 cubic centimeters of blood may cause fatal tamponade quickly if it escapes rapidly into the pericardium. On the other hand, a slow leak, as from an ice pick wound, may produce fatal tamponade several days later, as in Case A9. If the opening in the pericardium is of such size and location as to permit free and unimpeded flow to the exterior or into the pleura, tamponade does not occur but fatal hemorrhage ensues unless it is checked. As might be expected, many patients with large cardiac wounds and massive hemorrhage succumb before surgical aid is available. Death may occur in the hospital during the few minutes that it takes to make the diagnosis and start operation, even with the best organization.

Often the two conditions, tamponade and hemorrhage, occur simultaneously when the hole in the pericardium allows large quantities of blood to escape but not fast enough to decompress the rapidly filling pericardium. Occasionally, tamponade and extrapericardial bleeding occur alternately. In 2 cases in our series, increasing tamponade was evident until the intrapericardial pressure apparently reached the point where it could force open the communicating wound into the pleura. Spontaneous drainage into the pleura relieved the symptoms of tamponade, which recurred however, within a few minutes. Several such cycles were observed and, in 1 patient, could be brought about by changing position, which probably opened the wound in the pericardium. In a small proportion of cases, bleeding from the heart is small in amount and ceases spontaneously. If the pericardial opening in such cases allows decompression, recovery will ensue without surgical treatment.

Cerebral damage may occur as a result of emboli thrown off from mural thrombi in the

cardiac chambers, or as a result of cerebral anoxemia produced by neglected tamponade. The intracranial pressure closely parallels the high venous pressure and, in Case A1 of our series, reached 400 millimeters of spinal fluid. This high intracranial pressure and coexisting low blood pressure reduce the flow of blood through the brain so that harmful and even fatal cerebral anoxemia may occur. Extrapericardial hematomas may produce enough compression of the heart to give rise to tamponade. Such hematomas most frequently arise from division of the internal mammary artery, as in Cases C1, C4, and C7.

DIAGNOSIS

The diagnosis depends primarily upon an alert house staff keeping in mind the possibility of cardiac injury in every case of wound of the chest, no matter how trivial. This is especially true when the evidence of shock is out of proportion to the apparent severity of the wound or loss of blood. Acute alcoholism often clouds the picture and, in our series, was present in all but 2 cases. When acute tamponade is present, Beck's triad of acute cardiac compression is found. This triad consists of (a) falling arterial pressure, (b) rising venous pressure, and (c) small, quiet heart. (4) The patient appears to be in shock. The blood pressure, and particularly the pulse pressure, are low or unobtainable. The pulse is weak but not so rapid as might be expected unless there is considerable hemorrhage. Heart sounds are weak and distant. Increased venous pressure is evidenced by distended neck veins and cyanosis is often present. Direct measurement of the venous pressure at the elbow, by use of a water spinal manometer filled with 2½ per cent sodium citrate or normal saline solution, shows an increase often to 250 millimeters or more. Delirium, stupor, unconsciousness, or hemiplegia may occur, due to alcoholism, cerebral anoxemia, or emboli. Fluoroscopy is of the greatest value in diagnosis and clearly shows diminished or absent pulsation of the heart shadow. If available, a roentgen kymogram is of great aid.

When massive cardiac hemorrhage into the pleura is occurring, the exact diagnosis of

PENETRATING WOUNDS OF THE HEART AND PERICARDIUM

R. ARNOLD GRISWOLD M.D. F.A.C.S. and CHARLES HUGH MAGUIRE, M.D.
Louisville, Kentucky

WOUNDS of the heart were recognized in Homeric times, but none was successfully sutured until 1896. The history of the intervening 1500 or so years of speculation, experiment, and trial has been related by Ricketts, Cutler and Beck and by Elkin (10) and need not be repeated here. Since the first successful operation by Rehn in 1896 the recognition and treatment of this condition has become more frequent, until today hardly a month goes by without the report of successful suture of a cardiac wound. Review of the many single case reports in the literature probably gives an optimistic view of the mortality since unsuccessful single cases are seldom reported. The results of a questionnaire sent out by Bigger (5) to the members of the American Association for Thoracic Surgery, the American Surgical Association, and the Southern Surgical Association showed a mortality of approximately 50 per cent in 141 patients. Bigger (6) and Elkin (10) have reported series of 25 and 38 cases with mortality of 36 and 42 per cent in those cases which presented an opportunity for diagnosis and treatment. Prior to 1933 3 wounds of the heart were recognized and operated upon at the Louisville City Hospital by Sherrill in 1913 Hill (7) in 1926 and Cox in 1927 the last case having successful termination. Since 1933 from 2 to 8 cases have been seen yearly. This large number probably indicates not so much an increase in the number of heart wounds as it does an increased awareness of and interest in, the condition, since the diagnosis depends primarily upon keeping in mind the possibility of cardiac injury in every case of wound of the thorax. Elkin states that at Emory University 2 per cent of the pen-

etrating wounds of the chest injured the heart. In Bigger's experience 0.1 per cent of admissions to his surgical service in Richmond are wounds of the heart. These figures closely approximate our findings at the Louisville City Hospital.

PATHOLOGY

Wounds of the heart may of course, be caused by any sharp instrument or projectile. The weapon and the type of wound vary according to the local customs of the civilian population, or current military practice. In our experience, the knife, pistol and ice pick have been the most frequent weapons. A weapon or projectile may reach the heart from an entrance anywhere on the chest or even the upper abdomen. In most cases, however the wound of entrance is between the second and seventh left costal cartilages anteriorly usually traversing the left pleura. Occasionally the heart is reached from a wound of the posterior thorax. The right ventricle is the most frequently injured on account of its anterior position. Next in order of frequency are the left ventricle, the auricles, and the intrapericardial portions of the great vessels. Sucking wounds of the pleura are not uncommon. Injury to the peripheral portion of the lungs is frequent but usually of little moment.

Wounds of the heart may or may not penetrate the cavities. Bleeding from coronary vessels and the heart muscle, while not so profuse as when the chambers are opened, is surprisingly brisk and may be rapidly fatal. The consequences of cardiac hemorrhage are due in the main, to tamponade and exsanguination. The alternative between tamponade and exsanguination depends upon the relative flow capacities of the cardiac wound and the opening in the pericardium. Blood escaping from the heart fills the pericardium

and increases the intrapericardial pressure if denied free egress. Compression of the great veins at the base of the heart backs up the venous inflow and compensatory increase in venous pressure results. The blood pressure falls and the systolic and diastolic pressures tend to approximate each other because the heart is handling less blood. When the increasing venous pressure cannot overcome the intrapericardial pressure, circulatory arrest occurs. As little as 200 cubic centimeters of blood may cause fatal tamponade quickly if it escapes rapidly into the pericardium. On the other hand, a slow leak, as from an ice pick wound, may produce fatal tamponade several days later, as in Case 19. If the opening in the pericardium is of such size and location as to permit free and unimpeded flow to the exterior or into the pleura, tamponade does not occur but fatal hemorrhage ensues unless it is checked. As might be expected, many patients with large cardiac wounds and massive hemorrhage succumb before surgical aid is available. Death may occur in the hospital during the few minutes that it takes to make the diagnosis and start operation, even with the best organization.

Often the two conditions, tamponade and hemorrhage, occur simultaneously when the hole in the pericardium allows large quantities of blood to escape but not fast enough to decompress the rapidly filling pericardium. Occasionally, tamponade and extrapericardial bleeding occur alternately. In 2 cases in our series, increasing tamponade was evident until the intrapericardial pressure apparently reached the point where it could force open the communicating wound into the pleura. Spontaneous drainage into the pleura relieved the symptoms of tamponade, which recurred however, within a few minutes. Several such cycles were observed and, in 1 patient, could be brought about by changing position, which probably opened the wound in the pericardium. In a small proportion of cases, bleeding from the heart is small in amount and ceases spontaneously. If the pericardial opening in such cases allows decompression, recovery will ensue without surgical treatment.

Cerebral damage may occur as a result of emboli thrown off from mural thrombi in the

cardiac chambers, or as a result of cerebral anoxemia produced by neglected tamponade. The intracranial pressure closely parallels the high venous pressure and, in Case 11 of our series, reached 400 millimeters of spinal fluid. This high intracranial pressure and coexisting low blood pressure reduce the flow of blood through the brain so that harmful and even fatal cerebral anoxemia may occur. Extrapericardial hematomas may produce enough compression of the heart to give rise to tamponade. Such hematomas most frequently arise from division of the internal mammary artery, as in Cases C1, C4, and C7.

DIAGNOSIS

The diagnosis depends primarily upon an alert house staff keeping in mind the possibility of cardiac injury in every case of wound of the chest, no matter how trivial. This is especially true when the evidence of shock is out of proportion to the apparent severity of the wound or loss of blood. Acute alcoholism often clouds the picture and, in our series, was present in all but 2 cases. When acute tamponade is present, Beck's triad of acute cardiac compression is found. This triad consists of (a) falling arterial pressure, (b) rising venous pressure, and (c) small, quiet heart (4). The patient appears to be in shock. The blood pressure, and particularly the pulse pressure, are low or unobtainable. The pulse is weak but not so rapid as might be expected unless there is considerable hemorrhage. Heart sounds are weak and distant. Increased venous pressure is evidenced by distended neck veins and cyanosis is often present. Direct measurement of the venous pressure at the elbow, by use of a water spinal manometer filled with 2½ per cent sodium citrate or normal saline solution, shows an increase often to 250 millimeters or more. Delirium, stupor, unconsciousness, or hemiplegia may occur, due to alcoholism, cerebral anoxemia, or emboli. Fluoroscopy is of the greatest value in diagnosis and clearly shows diminished or absent pulsation of the heart shadow. If available, a roentgen kymogram is of great aid.

When massive cardiac hemorrhage into the pleura is occurring, the exact diagnosis of

Fig. 1. A transverse incision is made over the interspace where the wound of entrance is located and the wound of entrance is excised with the incision. The vertical portion upward, downward or both is added later if necessary. Incision is always made on the left, except when the wound of entrance is far to the right.

Fig. 2. After clearing of soft parts from the costal cartilage, Doyen's respiratory is introduced about the cartilage, close to the sternum, and poised slightly in lateral direction. This strips the soft tissues from the rib and enables one to do rapid resection without injuring the pleura or the internal mammary artery slice, if correctly inserted, the instrument invariably enters the proper plane of cleavage superficial to the pleura.

wound of the heart may be more difficult, but the indications for immediate operative intervention are clear and imperative. Bleeding from the parenchyma of the lung in wounds of the thorax may be massive but is slow and seldom requires operative hemostasis. On the other hand free bleeding from the heart, great vessels internal mammary or intercostal arteries is fast and profuse. Rapidly progressive shock is present early and death may quickly ensue unless hemorrhage is checked. We believe, therefore, that in the presence of increasing hemothorax and rapidly progressive fall in blood pressure, particularly with a precordial wound, exploration should be carried out at once, for even though the heart be intact, the arrest of hemorrhage from other structures is imperative.

TREATMENT

Once the diagnosis and the decision to intervene are made operation should be immediate and no preoperative treatment for shock or other condition should be allowed to delay operation. Intravenous fluids, particularly blood, should be administered when hemorrhage has occurred but are of little value preoperatively in case of tamponade. Morphine

is used sparingly particularly in the presence of alcoholism and tamponade because of its effect upon an already depressed respiratory center. Aspiration of the pericardium as recommended by Bigger may be a lifesaving measure to tide the patient over while preparations are made for operation. Speed, but not haste, in preparing for operation is essential. Every large general hospital should have available at all times a sterile setup of instruments and linens, and the operating room, with at least one nurse and orderly in attendance, should be open 24 hours a day. No short cuts should be taken however in the scrub up of the team or the preparation of the field of operation. Undue haste here may be followed by empyema and pericarditis later. We have had no deaths from infection and believe that this is the result of the same careful preparation as is used for any elective procedure.

A minimum of inhalation anesthesia is advisable, although oxygen under positive pressure is usually necessary on account of

the open pleura. The soporific effects of shock, tamponade, or alcoholism are generally present, but deeper anesthesia is often necessary after the release of tamponade. Our preference is for intercostal novocain block, usually of the third to sixth nerves, supplemented by oxygen and the minimum of nitrous oxide.

The incision should be one which permits rapid and adequate exposure of the heart and is made to the left of the sternum unless the wound of entrance is far to the right. This is best accomplished by a generous transverse incision over the interspace in which the wound is located. The wound of entrance is excised with this incision. The transverse incision may be joined, when necessary, by a vertical incision over the sternum (Fig 1). The costal cartilages above and below the incision are exposed and resected with about 1 inch of rib, by the method described by Meyer. "Previously, subperiosteal resection of the ribs with a pleura often as thin as a spider's web, was a task, especially in a moribund patient, extremely trying. The operation must be carried out with meticulous care and yet with great rapidity. However, one can resect the ribs in a few seconds and the steps of the operation are simple and the pleura is not opened or injured. The sternum must be exposed more than usual. The raspatory is introduced quite close to the sternum at the cartilaginous portion of the rib. This takes only a few seconds. Fat lies beneath, loose, and can readily be pushed aside. Here the Doyen raspatory is brought into play.

"It is inserted medial to the internal mammary artery and when pushed further in a lateral direction we resect the ribs extrapleurally as far as necessary and without danger to the pleura, because in this layer, the pleura is surprisingly easy to remove" (Fig 2). The internal mammary vessels are ligated and divided and the triangularis muscle and endothoracic fascia opened. The pleura is reflected from the pericardium by blunt dissection, beginning at the lower angle of the wound. Often this may be done by inserting the finger between the pericardium and pleura in the triangle of safety where the pericardium is uncovered by pleura. The

Fig 3 Autotransfusion outfit used in all cases of hemorrhage into body cavities. *a*, Pool suction tip, *b*, 500 cubic centimeter bottle with two-hole stopper containing citrate solution, *c*, tube running to operating room suction, *d*, 1000 cubic centimeter graduate, *e*, funnel with gauze filter, *f*, intravenous outfit with Murphy drip.

finger is then swept cephalad, easily separating the two structures. As much as necessary of the sternum is rongeured away. If additional exposure seems advisable on account of an oblique wound, the vertical limb is added to the incision upward, downward, or both, turning back triangular flaps which allow the removal of additional cartilages. If tamponade is present, the blood-filled pericardium will be tense, blue, and quiet. If the opening in the pericardium is large, it may usually be exposed and is best enlarged with the least damage to the heart, by gently but firmly spreading it with the fingers. If no opening is seen, the pericardium is nicked carefully after lifting it with forceps or stay sutures and this opening spread as above.

Clots are quickly scooped out of the pericardium with the fingers and liquid blood removed by suction into the autotransfusion outfit (Fig 3). With release of the tamponade the force and rate of the heart beat increase and bleeding becomes profuse, so that continuous suction is used from now on until the heart has been sutured.

Unless the wound is immediately visible and easily accessible, it is best to ignore the bleeding and insert a fine silk traction suture into the apex as advocated by Beck (2). There is nothing more disconcerting than to hold in

Fig. 4. Traction suture at apex, standing heart. A silk suture is being passed under finger which has been placed over the wound. Insert shows method of inserting mattress suture to avoid coronary vessel when wound is close to vessel.

One's hand a writhing jumping heart and vainly attempt to find a wound deep in a swirling whirlpool of blood. The insertion of a traction suture converts this stage of the operation from futile blundering into an orderly process. The traction suture steadies the jumping organ so that a finger may be placed over the opening temporarily to staunch the flow. A word of warning to those inexperienced in cardiac surgery is necessary at this point. If held rigidly the traction suture cuts through the myocardium with each systolic contraction. The hand holding the suture must therefore relax elastically with each beat, steadying but not fixing the heart. The finger must be placed over but not into the wound. One's natural tendency to insert the finger as a cork will only result in further laceration of the myocardium.

With the finger over the wound as temporary patch, a fine silk suture threaded on a French eye needle is inserted across the wound beneath the finger (Fig. 4). Slight traction on this suture holds the wound closed after the finger is removed and allows other

necessary sutures to be inserted. None of these sutures must be so deep as to penetrate the endocardium, on account of the increased risk of mural thrombi. They should be tied only tight enough to give hemostasis and must avoid strangulation of the muscle. Injured coronary vessels may be covered with a small patch of pectoral muscle (3) if the vessel is not completely severed. Complete division of large coronary arteries requires ligation by suture. Never attempt to grasp a bleeding coronary vessel with a hemostat. The closure of wounds close to large coronary vessels may present a problem. In Case A14 death resulted from occlusion of a large coronary vessel by the suture. This may be avoided easily by an "on-end" mattress suture beneath the vessel, as shown in Figure 4 insert.

If the wound is on the right or posterior portion of the ventricles, it may usually be exposed by appropriate traction on the suture at the apex. If necessary additional traction sutures well up on the ventricle may be used to rotate the heart to bring posterior wounds into view (Fig. 5).

Hemorrhage from wounds of the auricles and great vessels may be controlled temporarily by a soft clamp such as the Trendelenburg artery clip or the Horsley arterio-venous fistula clamp, or even with ordinary hemostats prior to the placing of sutures.

The blood collected in the autotransfusion bottles should, by now be running into the patient's veins. Any remaining blood in the pericardium and pleura is thoroughly sucked out for reabsorption. Autotransfusion in amounts up to 2500 cubic centimeters has been used in 14 of our cases. With the use of the apparatus illustrated it is a simple rapid procedure which is often life saving.

If there is already a free opening between the pericardium and pleura, this is left open and enlarged if necessary to allow adequate postoperative decompression of the pericardium into the pleura (11). This permits drainage of any remaining blood, as well as the increased pericardial fluid, which occurs after any operation upon the heart. Drainage to the exterior presents a real danger of infection as the draining fluid is sucked in and out of the drainage tract with each respiration.

The anterior pericardium is closed loosely with interrupted fine silk sutures. Tight closure is unnecessary and may be impossible or even harmful because of the cardiac dilatation which frequently occurs in these cases (1, 10). Soft tissues of the thoracic wall are closed firmly in layers with interrupted fine silk and the wound sealed with silver foil, after reinflation of the left lung by carefully applied positive pressure.

Recently, we have implanted up to 5 grams of powdered sulfanilamide or sulfathiazol into the pericardium and pleura before closure, as these wounds are all potentially infected.

Operation may sometimes be avoided in patients who have only mild tamponade and who do not have progressive intrapleural hemorrhage. These patients should, however, remain in the hospital and be confined strictly to bed until all danger of recurrent tamponade has passed. Frequently repeated observations of blood pressure, pulse, and venous pressure should be made, as well as daily fluoroscopic examination, since late tamponade may occur as in Cases A3, A9, A27. If tamponade is serious enough to require aspiration, as advocated by Bigger, open operation with wound suture and drainage of the pericardium into pleura is the treatment of choice.

POSTOPERATIVE TREATMENT

The patient is placed in an oxygen tent immediately after operation and is left there until his respiratory rate returns to normal. Fowler's position is usually the most comfortable and assists respiration. If shock has not been relieved by operation and autotransfusion, additional blood or plasma are indicated. Sufficient morphine should be administered to allay pain and restlessness, but not to depress respiration. Any remaining air and blood in the pleural cavity should be removed by thoracentesis to keep the lung expanded. This may be repeated at intervals as fluid reaccumulates, due to the irritating effect of blood on the serosa of the pericardium and pleura. The use of heparin, as suggested by Bigger, may be advisable, particularly when the weapon has pierced the endocardium. This may prevent deaths from embolism, such as occurred in Case A21.

Fig 5 Showing use of additional traction suture for rotating heart in either direction. Several such sutures may be used.

PROGNOSIS

The prognosis of wounds of the heart depends largely upon the character of the wound and the rapidity with which treatment is initiated. Undoubtedly, some patients die immediately because of disruption of the conducting mechanism of the heart. Many with large wounds succumb rapidly from hemorrhage before they can be transported to the hospital. This is particularly true of gunshot injuries with wounds of entrance and exit, often involving more than one chamber of the heart, as well as important extrapericardial structures. However, at least half the cases of massive hemorrhage and almost all the cases of tamponade, survive for an hour which, except in rural districts, should be time for transportation, diagnosis, and treatment. All patients, who died in the Louisville City Hospital before or during operation, were cases of hemorrhage, except 2 deaths from tamponade and 1 death on the table following occlusion of a major coronary artery. In those patients who survived operation, the most frequent fatal complication has been cerebral damage. This may be due to em-

bolism as in Case A21 or neglected tamponade and resultant cerebral anoxemia as in Cases A1, A4, A12 and A18. In those patients who lived the symptoms and signs of cerebral injury have disappeared spontaneously within a few months without leaving residual damage. No cases of fatal infection have been observed. It is our opinion that infection is most often caused by undue excitement and haste in preparation or by drainage of the pericardium externally. Clinical cardiac disability has been uniformly absent after operation and there has been no indication of reduced cardiac reserve. Electrocardiograph changes are usual following wounds of the heart, and vary from minor irregularities of the T wave to the typical picture of major coronary occlusion, as shown in Case A24. These abnormalities improve and sometimes even disappear within a few months. A detailed analysis of these changes is to be reported at a later time.

CASES

During the last 8 years, 47 patients with presumed or proved wounds of the heart have been admitted to the Louisville City Hospital. Fourteen of these have been reported previously in detail (1, 12, 13). Operations were performed by the senior author and, under his guidance, by the following resident surgeons at the Louisville City Hospital: J. M. Mayer, E. M. Driscoll, H. G. Saam, V. A. Badertscher, C. M. Bernhard, C. M. Schroeder, C. H. Maguire and E. S. Strode. In 7 cases the presumption that the heart was wounded was not borne out, but interesting cardiac aspects justify their inclusion in this report. Death occurred in 13 cases within 30 minutes of admission before operation could be started. In no case was operation delayed or refused, because of the moribund condition of the patient. Five of the patients operated upon were on the table within 30 minutes of admission, having been brought directly from the accident room. In the 27 cases which presented an opportunity for diagnosis and treatment, there were 7 deaths, a mortality of 25.9 per cent (Table I). Five were treated conservatively with 1 death. This patient refused to stay in the hospital and died of

tamponade on the eleventh day. Twenty-two patients were operated upon, with 6 deaths. Two of these deaths were due to hemorrhage, 1 on the table and 1 30 minutes after operation. One died on the table following ligation of a major coronary artery, and there were 3 deaths 18 hours, 48 hours, and 5 days after operation, due to cerebral complications. Our mortality has decreased with experience so that in the last 13 cases there has been but 1 death.

CASE A. W. M. A 32½ colored male, aged 30 years, with a ice pick wound in the left anterior axillary line in the sixth interspace seen in marked shock. No blood pressure was discernible, heart sounds were distant, pulse weak and 60 per minute. The patient had lacerated scalp and other ice pick wounds and was observed for 8 hours and then prepared for subtemporal decompression because of hemiplegia and unconsciousness that had developed. Spinal fluid pressure 400 mm. mercury. Fluoroscopic shadow of the round heart shadow. The pericardium was explored and ice pick wound of left ventricle with tamponade found. The patient never regained consciousness and died 8 hours after operation, with cerebral manifestations and terminal fever of 103° (3).

CASE A. J. D. A 29½ colored male, aged 29 years, as sent directly from the emergency room to the operating room. There was a knife wound in the left anterior axillary line in the third interspace. The patient was in marked shock, no blood pressure obtainable. Exploration revealed 1 by ½-inch laceration in the left ventricle and 3500 cubic centimeters of blood in the left pleural cavity. He died on the operating table from exsanguination (3).

CASE A3. W. J. A3 77½ colored male, aged 37 years, was seen with a stab wound in the seventh interspace, 2 centimeters to the left of the sternum. Blood pressure was 98/70. Roentgenogram showed slight enlargement of heart shadow. On the second day the patient collapsed on getting out of bed and went into extreme shock; he recovered slowly. The same thing was repeated on the fourth day. He was discharged on the twelfth day and readmitted 6 days later with edema of scrotum and legs, distant heart sounds and enlarged shadow. Uneventful recovery took place (1).

CASE A4. V. H. 34 95 colored male, aged 38 years, with a stab wound in the left anterior axillary line at the level of the sixth rib was admitted in marked shock. He improved under observation. X-ray picture showed wide heart shadow. Patient was observed for 4 hours and then exploration operation carried out because of development of paradoxical pulse and right-sided twitches. Laceration of posterolateral wall of left ventricle was found and sutured. Recovery took place. Patient discharged on the thirty-fifth day (1).

CASE A5 W C, 34388, white male, aged 11 years, with .22 caliber rifle wound in fourth interspace 3 centimeters to the right of the sternum was seen in marked shock. No blood pressure was obtainable, pulse was 70, heart sounds distant. Fluoroscopy revealed slight enlargement of the heart shadow. A laceration in the upper lateral portion of the right ventricle was closed. Patient was discharged on the thirty-fifth day (13).

CASE A6 J S, 38543, colored male, aged 35 years, was stabbed in the right chest with scissors. Sucking wound was present in the fourth interspace. Blood pressure varied greatly on observation. Venous pressure was 150 millimeters of water. X-ray film of chest revealed hemopneumopericardium with a definite fluid level. His hospital course was uneventful and patient was discharged on seventeenth day (13).

CASE A7 C T, 43640, colored male, aged 26 years, with gunshot wound in the fifth interspace in the left anterior axillary line was seen in marked shock. No blood pressure was obtainable, heart sounds were distant, pulse 80 per minute. Wound in the lower portion of the left ventricle was found and sutured. No wound of exit was found. Recovery was uneventful. Patient was discharged on the forty-second day. X-ray film showed bullet in right iliac artery. Distal pulsation was absent but circulation adequate (12).

CASE A8 T R, 44460, colored male, aged 17 years, with laceration of chest, beginning in left fifth interspace in midclavicular line and extending across sternum to 2 centimeters on right was in moderate shock. Blood pressure was 74/50, pulse, 100 per minute. Patient was operated upon within 45 minutes after admission. Laceration of right auricle was found and sutured, but patient had lost too much blood and died 30 minutes after operation (12).

CASE A9 A C, 44937, white female, aged 29 years, was stabbed repeatedly with an ice pick. There was subcutaneous emphysema throughout most of the chest wall. Fluoroscopy showed enlarged cardiac shadow with decrease in pulsation. Patient refused to stay in hospital and died 11 days after injury while straining at stool. Autopsy revealed a puncture wound of the left auricle that had apparently oozed slowly and caused fatal tamponade (12).

CASE A10 E H, 43909, colored male, aged 48 years, with 4 stab wounds in the third interspace on the left was in marked shock. Blood pressure was 46/40, heart sounds, distant, pulse, paradoxical and 80 per minute. Fluoroscopy showed enlarged heart shadow. Three lacerations in the left ventricle were sutured, and recovery was uneventful. Patient was discharged on the thirty-fourth day (12).

CASE A11 F W, A52994, colored female, aged 28 years, was seen with stab wound in the sixth interspace just to left of sternum. Neck and arm veins were distended. Patient was in moderate shock, blood pressure was 80/60, heart sounds,

muffled, pulse paradoxical and 100 per minute. Laceration of right ventricle sutured. Recovery was uneventful. Patient was discharged on the twenty-sixth day.

CASE A12 L R, 1623, white male, aged 27 years, was seen with 6 centimeter laceration in the fourth interspace in the precordium. Heart sounds were distant, blood pressure, 40/0, pulse, 80 per minute. Neck veins were distended. Internal mammary and right auricle were lacerated. They were sutured successfully but patient remained unconscious and died at end of 48 hours with a terminal fever of 108 degrees, due either to cerebral anoxemia or post-operative heat stroke. Autopsy showed the heart wounds to be sutured satisfactorily.

CASE A13 E C, 2322, colored male, aged 23 years, with stab wound in right fourth interspace 4 centimeters from sternum was seen in marked shock. Blood pressure was unobtainable, heart sounds, quite distant, pulse, weak and recorded as 40 per minute. Laceration of right ventricle on the upper anterior aspect found and sutured. Recovery was uneventful. It is interesting, in this case, that there was moderate bleeding to the outside and when operation was carried out, it was found that there was obliteration of both pleural cavities. Patient was discharged on the twenty-sixth day.

CASE A14 M L, 26018, colored female, aged 20 years, with stab wound in fourth interspace 2 centimeters to left of sternum was seen in marked shock. Blood pressure was unobtainable, heart sounds, distant, pulse, weak, 60 per minute. Laceration of right ventricle was adjacent to the descending coronary artery. Coronary vessels were tied during suture of the wound. Typical acute cardiac dilatation and death on the table followed (1).

CASE A15 C B, 26804, colored male, aged 34 years, with transverse laceration that involved the seventh and eighth costal cartilages and nicked the sternum was seen in marked shock. Blood pressure was unobtainable, no radial pulse palpable, heart sounds quite distant, 100 per minute. Laceration of the midportion of the right ventricle was sutured. Recovery was uneventful. Patient was discharged on the eighteenth day.

CASE A16 B A, 3088, colored male, aged 34 years, with stab wound in the sixth interspace just to the left of the sternum was seen in moderate shock. Blood pressure was 94/64, pulse, 96 per minute, neck veins, distended, venous pressure, 250 millimeters of water, heart sounds, muffled. Fluoroscopy revealed enlarged nonpulsatile shadow. Laceration of tip of the anterior surface of the right ventricle was sutured. Recovery was uneventful. Patient was discharged on the eighteenth day.

CASE A17 E G, 29910, white female, aged 36 years, had received three ice pick wounds in the third interspace just to right of sternum, also a wound in the posterior chest just to the left of the vertebrae. Blood pressure was 70/50, pulse, 120 per minute, neck veins, distended, venous pressure, 200 millimeters of water, heart sounds, distant, patient

bolism as in Case A21 or neglected tamponade and resultant cerebral anoxemia, as in Cases A1 A4 A12 and A18. In those patients who lived the symptoms and signs of cerebral injury have disappeared spontaneously within a few months without leaving residual damage. No cases of fatal infection have been observed. It is our opinion that infection is most often caused by undue excitement and haste in preparation or by drainage of the pericardium externally. Clinical cardiac disability has been uniformly absent after operation and there has been no indication of reduced cardiac reserve. Electrocardiograph changes are usual following wounds of the heart, and vary from minor irregularities of the T wave to the typical picture of major coronary occlusion as shown in Case A24. These abnormalities improve and sometimes even disappear within a few months. A detailed analysis of these changes is to be reported at a later time.

CASES

During the last 8 years, 47 patients with presumed or proved wounds of the heart have been admitted to the Louisville City Hospital. Fourteen of these have been reported previously in detail (1-13). Operations were performed by the senior author and, under his guidance, by the following resident surgeons at the Louisville City Hospital: J. M. Mayer, E. M. Drissen, H. G. Saam, V. A. Badertscher, C. M. Bernhard, C. M. Schroeder, C. H. Maguire and E. S. Strode. In 7 cases, the presumption that the heart was wounded was not borne out, but interesting cardiac aspects justify their inclusion in this report. Death occurred in 13 cases within 30 minutes of admission before operation could be started. In no case was operation delayed or refused, because of the moribund condition of the patient. Five of the patients operated upon were on the table within 30 minutes of admission, having been brought directly from the accident room. In the 27 cases which presented an opportunity for diagnosis and treatment there were 7 deaths, a mortality of 25.9 per cent (Table I). Five were treated conservatively with 1 death. This patient refused to stay in the hospital and died of

tamponade on the eleventh day. Two of these deaths were 1 on the table and 1 30 minutes after admission. One died on the table of a major coronary artery aneurysm. In 18 hours, 48 hours after operation, due to cerebral anoxemia mortality has decreased so that in the last 13 cases there was 1 death.

CASE A1. W. M. A25, 33 years, with ice pick wound of the sixth intercostal space, marked shock. No blood pressure, heart sounds were distant, pulse minute. The patient had 12 other ice pick wounds and was operated on and then prepared for subtemporal craniotomy because of hemiplegia and aphasia developed. Spinal fluid pressure 18 mm. Fluoroscopic shadow showed the pericardium was entered, wound of left ventricle. 15th tamponade. patient never regained consciousness after operation. 15th cerebral and terminal fever of 103° (3).

CASE A2. J. D. A29, 33 years, was sent directly from the accident room to the operating room. There was a 1/2 inch left anterior axillary line in the third intercostal space. marked shock, no blood pressure obtainable. Exploration revealed laceration of the left ventricle and 1/2 inch of blood in the left pleural space. The patient died on the operating table from exsanguination.

CASE A3. W. J. A31, 77 years, colored, was seen with stab wound of the left chest, 1/2 inch, 1/2 inch from the left. Blood pressure was 95/70. Roentgen shadow showed enlargement of heart shadow. The patient collapsed on getting into the operating room. He recovered after extreme shock. The same thing was repeated on the fourth day. He was discharged on the fifth day, but later with edema of scrotum and legs. He died of uremia. Recovery took place (2).

CASE A4. V. H. 34, 95 colored, years, with stab wound of the left chest at the level of the sixth rib, a 1/2 inch, marked shock. He improved under X-ray picture showed no heart shadow was observed for 22 hours and the operation carried out because of development of paradoxical pulse and right-sided twist of the abdomen. All of left chest was found and sutured. Recovery took place. He was discharged on the thirty-fifth day.

CASE A5 W C, 34388, white male, aged 11 years, with 22 caliber rifle wound in fourth interspace 3 centimeters to the right of the sternum was seen in marked shock. No blood pressure was obtainable, pulse was 70, heart sounds distant. Fluoroscopy revealed slight enlargement of the heart shadow. A laceration in the upper lateral portion of the right ventricle was closed. Patient was discharged on the thirty-fifth day (13).

CASE A6 J S, 38543, colored male, aged 35 years, was stabbed in the right chest with scissors. Sucking wound was present in the fourth interspace. Blood pressure varied greatly on observation. Venous pressure was 150 millimeters of water. X-ray film of chest revealed hemopneumopericardium with a definite fluid level. His hospital course was uneventful and patient was discharged on seventeenth day (13).

CASE A7 C T, 43640, colored male, aged 26 years, with gunshot wound in the fifth interspace in the left anterior axillary line was seen in marked shock. No blood pressure was obtainable, heart sounds were distant, pulse 80 per minute. Wound in the lower portion of the left ventricle was found and sutured. No wound of exit was found. Recovery was uneventful. Patient was discharged on the forty-second day. X-ray film showed bullet in right iliac artery. Distal pulsation was absent but circulation adequate (12).

CASE A8 T R, 44460, colored male, aged 17 years, with laceration of chest, beginning in left fifth interspace in midclavicular line and extending across sternum to 2 centimeters on right was in moderate shock. Blood pressure was 74/50, pulse, 100 per minute. Patient was operated upon within 45 minutes after admission. Laceration of right auricle was found and sutured, but patient had lost too much blood and died 30 minutes after operation (12).

CASE A9 A C, 44937, white female, aged 29 years, was stabbed repeatedly with an ice pick. There was subcutaneous emphysema throughout most of the chest wall. Fluoroscopy showed enlarged cardiac shadow with decrease in pulsation. Patient refused to stay in hospital and died 11 days after injury while straining at stool. Autopsy revealed a puncture wound of the left auricle that had apparently oozed slowly and caused fatal tamponade (12).

CASE A10 E H, 43909, colored male, aged 48 years, with 4 stab wounds in the third interspace on the left was in marked shock. Blood pressure was 46/40, heart sounds, distant, pulse, paradoxical and 80 per minute. Fluoroscopy showed enlarged heart shadow. Three lacerations in the left ventricle were sutured, and recovery was uneventful. Patient was discharged on the thirty-fourth day (12).

CASE A11 F W, 452004, colored female, aged 28 years, was seen with stab wound in the sixth interspace just to left of sternum. Neck and arm veins were distended. Patient was in moderate shock, blood pressure was 80/60, heart sounds,

muffled, pulse paradoxical and 100 per minute. Laceration of right ventricle sutured. Recovery was uneventful. Patient was discharged on the twenty-sixth day.

CASE A12 L R, 1623, white male, aged 27 years, was seen with 6 centimeter laceration in the fourth interspace in the precordium. Heart sounds were distant, blood pressure, 40/0, pulse, 80 per minute. Neck veins were distended. Internal mammary and right auricle were lacerated. They were sutured successfully but patient remained unconscious and died at end of 48 hours with a terminal fever of 108 degrees, due either to cerebral anoxemia or post-operative heat stroke. Autopsy showed the heart wounds to be sutured satisfactorily.

CASE A13 E C, 2322, colored male, aged 23 years, with stab wound in right fourth interspace 4 centimeters from sternum was seen in marked shock. Blood pressure was unobtainable, heart sounds, quite distant, pulse, weak and recorded as 40 per minute. Laceration of right ventricle on the upper anterior aspect found and sutured. Recovery was uneventful. It is interesting, in this case, that there was moderate bleeding to the outside and when operation was carried out, it was found that there was obliteration of both pleural cavities. Patient was discharged on the twenty-sixth day.

CASE A14 M L, 26018, colored female, aged 20 years, with stab wound in fourth interspace 2 centimeters to left of sternum was seen in marked shock. Blood pressure was unobtainable, heart sounds, distant, pulse, weak, 60 per minute. Laceration of right ventricle was adjacent to the descending coronary artery. Coronary vessels were tied during suture of the wound. Typical acute cardiac dilatation and death on the table followed (1).

CASE A15 C B, 26804, colored male, aged 34 years, with transverse laceration that involved the seventh and eighth costal cartilages and nicked the sternum was seen in marked shock. Blood pressure was unobtainable, no radial pulse palpable, heart sounds quite distant, 100 per minute. Laceration of the midportion of the right ventricle was sutured. Recovery was uneventful. Patient was discharged on the eighteenth day.

CASE A16 B A, 3088, colored male, aged 34 years, with stab wound in the sixth interspace just to the left of the sternum was seen in moderate shock. Blood pressure was 94/64, pulse, 96 per minute, neck veins, distended, venous pressure, 250 millimeters of water, heart sounds, muffled. Fluoroscopy revealed enlarged nonpulsatile shadow. Laceration of tip of the anterior surface of the right ventricle was sutured. Recovery was uneventful. Patient was discharged on the eighteenth day.

CASE A17 E G, 29910, white female, aged 36 years, had received three ice pick wounds in the third interspace just to right of sternum, also a wound in the posterior chest just to the left of the vertebrae. Blood pressure was 70/50, pulse, 120 per minute, neck veins, distended, venous pressure, 200 millimeters of water, heart sounds, distant, patient

In mild shock. Fluoroscopy revealed enlarged nonpulsatile shadow. Wound in anterior portion of the sternum just above the valves was closed with silk suture. Recovery was uneventful. Patient was discharged on the fifteenth day.

CASE A 8. L. S. 385 colored male, aged 3 years, walked into the emergency room and collapsed. He was in marked shock. Patient had received stab wound in the fourth interspace 4 centimeters to left of the sternum. Blood pressure was 78/60 pulse, 20 per minute. There was slight venous distention. Venous pressure, 100 millimeters of water, heart sounds of fair quality. Fluoroscopy showed large nonpulsatile shadow and kymogram limitation of ventricular excursion. There was laceration in the left ventricle with hematoma over the anterior descending branch of the left coronary vessels. Infection of skin flaps developed and then osteomyelitis of the ends of the fourth and fifth ribs. There also developed a left facial weakness. Patient was discharged in 57 days with both these conditions cleared up.

CASE A 9. S. W. 586, colored male, aged 4 years, had received stab wound just to the left of the costal cartilage. Patient was in marked shock. Blood pressure, 44/0 muffled irregular cardiac sounds, pulse, 60 per minute, paradoxical in type. Neck veins were distended, and venous pressure 200 and 280 millimeters of water on successive readings. Fluoroscopy showed enlarged nonpulsatile shadow. Laceration of right ventricle on the anterior inferior aspect was sutured. Recovery as uneventful. Patient was discharged on the fifteenth day.

CASE A 20. A. B. L. 7704 colored male, aged 7 years, with stab wound in the fifth interspace just beneath the left pectoral fold was seen in profound shock. Blood pressure was 40/30 neck veins were distended venous pressure as 80 millimeters of water heart sounds distant pulse 60 per minute. Fluoroscopy revealed large nonpulsatile shadow. Laceration of the left ventricle 3 centimeters in length was sutured. Recovery was uneventful. Patient was discharged on the fifteenth day.

CASE A. J. W. H. 80030, colored male, aged 3 years, had received stab wound in the fifth interspace in left anterior axillary line. Blood pressure was 60/40 pulse 100 per minute. Neck veins were distended, venous pressure was 190 millimeters of water heart sounds distant with paradoxical pulse. Fluoroscopy showed enlarged nonpulsatile shadow. Laceration of lateral side of left ventricle was sutured. Patient died on the fifth day with complete right-sided hemiplegia. A autopsy showed large mural thrombus at the site of wound in endocardium and an embolus plugged left middle cerebral artery.

CASE A 2. L. J. 80755 colored male aged 16 years had received ice pick wound in the third interspace 5 centimeters to the left of the sternum and other wounds slightly above and lateral to this one. Patient was in shock. Blood pressure was 60/5 pulse 84 per minute. Heart sounds were distant there was slight venous distention venous

pressure was 11 millimeters of water. Fluoroscopy showed enlarged nonpulsatile shadow. Exploration revealed tamponade and wounds of the arch of the aorta. Recovery was uneventful. Patient was discharged on the thirteenth day.

CASE A 3. L. H. 80834 colored male aged 10 years with gunshot wound of left chest in the fourth interspace was seen in marked shock. Pressure was 40/0 pulse, 70 per minute neck veins, slightly distended venous pressure 80 millimeters of water no audible heart sounds. Fluoroscopy revealed wide nonpulsatile shadow and the bullet in the right lung. Exploration disclosed a fractured sternum and tamponade. The bullet had driven fragment of sternum into the wall of the right ventricle. Recovery was uneventful. Patient was discharged on the fourteenth day.

CASE A 24. J. D. H. 5196 colored male, aged 10 years with stab wound in the fourth interspace 4 centimeters to left of sternum was seen in marked shock. Blood pressure was unobtainable pulse 80 per minute. Patient was taken direct to operating room without fluoroscopy or venous pressure readings. A laceration of the left atrioventricular groove 4 centimeters in length which had severed the anterior descending branch of the left coronary artery was sutured. Recovery as uneventful. Patient was discharged on the thirty eighth day. Electrocardiogram showed typical anterior coronary block. This has improved to the present date.

CASE A 25. J. C. 804 colored male, aged 9 years, as admitted 7 hours after having been stabbed in the sixth interspace just posterior to anterior axillary line. Patient complained of occasional precordial pain, slight dyspnea, moderate venous distention. Venous pressure was 50 to 60 millimeters of water. Fluoroscopy showed wide cardiac shadow and kymogram showed decreased ventricular excursion. Patient was comfortable with exception of slight dyspnea. He was discharged on the ninth day.

CASE A 26. W. H. 5765 hit male aged 15 years with stab wound 1 centimeter medial and below left nipple was seen in moderate shock. Blood pressure was 80/4 pulse 100 and rapid heart sounds (aortic). Venous pressure as 60 millimeters of water. Fluoroscopy showed decreased pulsation. A hemothorax as present. Laceration of left ventricle 5 centimeters in length was sutured. Recovery was uneventful.

CASE A 27. J. T. 848 colored male, aged 5 years, was seen with stab wound in left third interspace 4 centimeters from midclavicular line and just below xyphoid at left costal margin. There was no shock. Blood pressure was 30/80 pulse 30. Venous pressure was 1 millimeters of water. Heart sounds were normal except for occasional splash. X-ray film showed hemopericardium. An operation was done. On the second day blood pressure was 86/60 and venous pressure 50 millimeters of water. Spontaneous improvement occurred, however and eventual recovery was good.

TABLE II

B	1941	M	34	Fatal	no data	R and L V	Hemothorax

the fifth rib, 7 cc thimera to right of sternum. There was 3000 cubic centimeters of blood in pleural cavities pericardium was full and there was a wound through both ventricles.

CASE B5. S W B8350 colored male, aged 3 years with stab wound of the first interspace 1 centimeter to left of sternum died on admission to emergency room. Autopsy revealed acute tamponade. Pericardial sac contained 200 cubic centimeters of blood. There were 600 cubic centimeters of blood in each pleural cavity. A laceration of the left ventricle near the atrioventricular groove was found.

CASE B6. T J B900 colored male, aged 24 years with stab wound of the sixth interspace 1.5 centimeters to left of sternum, died on admission to emergency room. Each pleural cavity contained 600 cubic centimeters of blood and pericardium was full. There was laceration of all of the left ventricle which extended into the interventricular septum.

CASE B7. C S B90063 colored male, aged 35 years with gunshot wound of the sixth rib 1 centimeter to left of sternum was dead on arrival. There was 400 cubic centimeters of blood in pericardium and approximately 600 cubic centimeters in each pleural cavity. There was through-and-through wound of the heart involving both ventricles and the septum.

CASE B8. J S., 1902, colored male, aged 24 years, with stab wound just below midportion of left clavicle, was dead on arrival. Both pleurae were full of blood, pericardium contained 60 cubic centimeters. There was a through-and-through laceration of the ascending aorta just above the valves.

CASE B9. D McC 78674 white male, aged 30 years, with stab wound of the fifth intercostal space 1/2 to left of sternum, arrived in emergency room

breathing but died by the time he reached the ward. Acute tamponade was present with 450 cubic centimeters of blood in pericardial sac and a 5 centimeter laceration in wall of right ventricle 1 centimeter from apex.

CASE B10. R G B8850, colored male, aged 43 years, had received gunshot wound of the sixth intercostal space 1 centimeter to left of sternum with wound of exit posteriorly 6 centimeters to left of midline at level of the twelfth rib. Patient expired in 15 minutes. There was wound of the right ventricle which was 3 centimeters from the apex and 600 cubic centimeters of blood was in each pleural cavity.

CASE B11. L B 8336 colored male, aged 41 years, with gunshot wound in anterior axillary line with no wound of exit, was dead on arrival. There was laceration of the aorta 6 centimeters above the valves with 500 cubic centimeters of blood in pericardial sac, 500 cubic centimeters of blood in left pleural cavity and 700 cubic centimeters in the right.

CASE B12. L E., 8364 colored male, aged 30 years, with gunshot wound of the second interspace in left midclavicular line expired on arrival. There was a wound along the wall of the left ventricle and of the posterior wall of the pulmonary artery. There was 500 cubic centimeters of blood in pericardium and 400 cubic centimeters of blood in each pleural cavity.

CASE B13. J P 37803 colored male, aged 4 years, had received gunshot wound of the left sternal border in the fifth intercostal space. Heart sounds were distant. There was no palpable pulse; blood pressure was not discernible. Patient died in 15 minutes like a prepared for operation. Through-and-through wound of both ventricles as present with hemothorax of 3000 cubic centimeters.

TABLE III

Case	Year	Sex	Age	Weapon	Result	Remarks
C1	1934	F	43	Knife	Lived	Venous pressure 250 extrapericardial hematoma
C2	1937	F	31	Pistol	Died	Wound of pericardium and diaphragm
C3	1937	M	25	Knife	Died	Internal mammary hemorrhage and hemothorax
C4	1937	M	9	Knife	Died	Internal mammary hemorrhage and extrapericardial hematoma
C5	1938	M	40	Knife	Lived	Acute cardiac dilatation
C6	1940	M	37	Pistol	Lived	Hemothorax
C7	1941	M	74	Pistol	Lived	Extrapericardial hematoma

Of the 7 cases in which the presumption of wound of the heart was not borne out at operation, 3 had tamponade due to the pressure of extrapericardial hematomas. In 2 there was massive intrapleural arterial hemorrhage and in 1 a wound of the pericardium and diaphragm but not of the heart. The most interesting of this group, Case C5, acute cardiac dilatation, relieved by pericardiotomy, has been discussed in detail by Badertscher (Table III).

CASE C1 H T, 38700, colored female, aged 43 years, with stab wound in the fourth interspace 5 centimeters to left of sternum was seen in moderate shock. Blood pressure was 68/20, pulse, 82 per minute, venous pressure, 250 millimeters of water. There was present a laceration of pericardium and about 100 cubic centimeters of blood in pericardium but no definite cardiac wound. However, there was a large extrapericardial hematoma from the internal mammary artery with pressure on the pericardium, causing tamponade. Course was uneventful. Patient was discharged on the twenty-fourth day.

CASE C2 E R, A57031, colored female, aged 31 years, had received pistol wound in the fifth interspace 1 centimeter to left of sternum, exit posteriorly in the seventh interspace. Patient was in marked shock. Blood pressure was unobtainable, heart sounds, distant, pulse, 100 per minute. Progress was progressively downward. Patient was taken to operating room after 2 hours, and exploration revealed an old adhesive pericarditis. The bullet had torn off some of the inferior part of the pericardium but there was no definite cardiac wound. The bullet had then perforated the diaphragm medial to the wound in the pericardium. Patient died 24 hours after operation, never coming out of shock.

CASE C3 C B, A59647, white male, aged 25 years, with sucking stab wound in left sixth interspace, was not in shock, but was explored because of position of the wound. Exploration revealed the left internal mammary artery severed but no heart wound. Patient died on the seventh day, apparently from secondary hemorrhage.

CASE C4 E R, A59647, colored male, aged 29 years, with stab wound in the third interspace 3

centimeters to right of sternum, was in marked shock. Blood pressure was 84/50, sounds were of good quality, there was slight venous distention. Exploration revealed the right internal mammary cut and 1000 cubic centimeters of blood in right chest. Patient died on the fourth day after operation.

CASE C5 W O S, 25733, colored male, aged 40 years, had received stab wound in the third interspace 2 centimeters to left of sternum. Blood pressure was 82/50, pulse, 70 per minute. Sounds were distant, slight venous distention was present, moderate shock. No pericardial wound was found but pericardium was quite tense and when it was cut the heart bulged into the opening and blood pressure came up to a normal level. Patient had an uneventful recovery and was discharged on the fifteenth day. (Discussed in detail by Badertscher.)

CASE C6 W H, 81802, white male, aged 32 years, with gunshot wound of the fifth interspace 5 centimeters to left of sternum, was seen in marked shock. Blood pressure was 40/20, pulse, 100 per minute, slight venous distention present. Fluoroscopic revealed no definite cardiac pulsation and the left chest was full of blood. No cardiac wound found on exploration. Left chest contained 1000 to 1500 cubic centimeters of blood. Patient signed out of hospital on the sixth day, but prior to that time his course had been uneventful.

CASE C7 S W, 14929, colored male, aged 24 years, with gunshot wound in the third interspace 5 centimeters to left of sternum, was seen in marked shock. Blood pressure unobtainable, slight venous distention present, pulse, 120 per minute. Fluoroscopic showed no definite cardiac pulsation. Operation disclosed no definite cardiac wound, but a hematoma from left internal mammary artery causing tamponade. Recovery was uneventful. Patient was discharged on the eleventh day.

SUMMARY

Reports of successfully treated wounds of the heart are becoming more frequent because of better diagnosis and more aggressive treatment. Death usually occurs from either massive hemorrhage or tamponade. Most of the patients who die before operation succumb

to hemorrhage usually due to gunshot wounds, although in our experience several patients with massive hemorrhage from gunshot wounds have survived following very early operative treatment. Patients with tamponade are much more likely to live long enough for treatment to be instituted and in only 2 of our preoperative deaths was this caused by tamponade. Of the 27 patients in our series who were alive 20 minutes after admission to the accident room, there were 7 deaths. This is a mortality of 25.9 per cent in those cases which presented an opportunity for diagnosis and treatment. That the results improve with experience is shown by the fact that in the last 13 of these cases, there has been but 1 death. Cerebral damage due either to embolism or to anoxemia from neglected tamponade has been the most frequent postoperative complication. No residual

cardiac disability has been observed in patients who recovered. Acute cardiac tamponade may be produced by extracardiac lesions, such as hematomas.

NONPENETRATING TRAUMA OF THE ABDOMEN

WILLIAM L. ESTES, Jr, A B, M D, Bethlehem, Pennsylvania

TRAUMA to the abdominal viscera without laceration or penetration of the abdominal wall or with incomplete penetration presents a particularly fascinating problem and challenge to the surgeon, because of (1) the high mortality attending laceration or rupture of the viscera, (2) the comparative infrequency with which the individual surgeon encounters abdominal trauma, (3) the frequent difficulty in making an accurate diagnosis of a serious lesion because of the apparently inconsequential or obscure initial symptoms, (4) the possibility of a variable latent period before evidence of extensive visceral damage appears, (5) the need for the recognition of the pitfalls in diagnosis and treatment if the extraordinarily high mortality is to be lowered

Injury to the abdomen may result in (1) a simple laceration or puncture of the abdominal wall, which does not perforate into the peritoneum, (2) a penetrating or perforating wound, (3) a contusion or subcutaneous rupture only of the abdominal wall, (4) a contusion, laceration, or rupture of an intra-abdominal organ or structure with no evidence of external injury, (5) any combination of the above four lesions (Levering)

Nonpenetrating trauma of the abdomen will include, then, a contusion or subcutaneous rupture of the abdominal wall, or a contusion, laceration, or rupture of intra-abdominal viscera or blood vessels, either without external injury or with a superficial unrelated nonpenetrating laceration

MORTALITY

Mortality in subcutaneous abdominal visceral trauma is high largely because of the frequency of multiple major injuries which are inevitably and rapidly fatal. However, the reported mortality rate in recent years has shown a definite decrease. This decrease

seems due to improvement in methods of diagnosis and better recognition of the therapeutic indications, especially the appropriate time for surgical interference

TABLE I — MORTALITY

Author	Years	No cases	Mortality per cent
Petersen	1885-1890		60-70
Petersen	1900		30
Demel	1933	126	21.9
	to		
Lewis and Trimble	1936	140	20
Just		79	13.9

INCIDENCE

The incidence of subcutaneous trauma of the abdomen as compared to injuries elsewhere in the body is low. In a 5 year period, 2217 injuries of all types were admitted to our clinic only 32 (1.4 per cent) of which had nonpenetrating abdominal trauma. Cody reports similarly 5744 accidental deaths in Iowa during a 3 year period, 53 (0.9 per cent) of which were the result of subcutaneous abdominal trauma. A higher rate of occurrence might be found in densely populated areas where the likelihood of this type of injury as a result of motor accidents would be greater. However, it is obvious that nonpenetrating abdominal trauma is not too frequently encountered except possibly in hospitals devoted largely to traumatic surgery

ETIOLOGY

Abdominal trauma may result from (1) an anteroposterior or a lateral squeezing, or a direct blow, crushing a viscus between the instrument of force and the spine or rupturing an organ or the diaphragm by a great increase of intra-abdominal pressure, (2) a tangential force, moving the bowel or other viscus beyond its limits of mobility causing tears in mesentery, etc., (3) compression of fluid or gas in a single loop of intestine, (4) fragments of pelvic bones, rupturing or puncturing the bladder and rectum, (5) falls at play, at work, or at home. Motor and indus-

From the Surgical Service, St. Luke's Hospital.
Presented before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

trial accidents, athletic injuries and falls in the home are the most frequent causes. Of Bailey's 100 cases, 76 were due to transportation accidents (60 motor) the 24 remaining to industrial or athletic accidents, or falls in the home.

PATHOLOGY

In mild cases, usually without evidence of superficial contusion there may be a hematoma deep in the abdominal muscles, secondary to a laceration of a muscle or a blood vessel, a retroperitoneal hematoma, hemorrhage into the mesentery or omentum or beneath the capsule of liver, spleen, or kidney or subserosal hemorrhage of stomach or intestine. It is this group that definitely may be treated conservatively. The frequency with which mild indeterminate trauma is found has been variously reported in 45 (30 per cent) of 140 cases by Lewis and Trimble, 41 (54 per cent) of 76 cases by Just, and 36 (38 per cent) of 94 cases in our series.

Crushing and severe injuries produce particularly laceration or rupture of the liver, spleen, pancreas, kidney, small or large intestine, stomach, diaphragm, bladder, gall bladder, omentum or mesentery often accompanied by fracture of the pelvis, spine or ribs. Numerous reports of obscure and rarer lesions have also been recorded such as (1) hemoperitoneum due to subcutaneous rupture of the iliac vein (2) mesenteric thrombosis (3) rupture of a gastric ulcer (4) avulsion of the gall bladder (5) pancreatic cyst (6) tuberculous peritonitis, following rupture of an intra-peritoneal tuberculous abscess.

DIAGNOSIS

The successful outcome of most cases hinges upon the sagacity and diagnostic acumen of the attending physician. Clinically abdominal trauma may be classified into three groups (1) severe multiple injuries which are rapidly fatal and for which no treatment is of avail (2) cases that obviously require immediate operation (3) cases in which the diagnosis is doubtful and the indications for or against operation are not clear.

In the proper care of this third group lies the greatest opportunity for saving lives and lowering the extraordinarily high mortality

rate. Very close and repeated observation is mandatory. At the earliest possible interval following the accident a decision must be reached whether or not the lesion demands immediate operation.

Aids toward an accurate diagnosis will be (1) the history (2) careful physical examination (3) blood count, blood protein estimations, urine examinations (4) radiography.

History. It seems generally agreed that force applied to a *limited* or circumscribed area of the abdomen is more prone to lacerate or rupture the intestine or kidney but force applied diffusely over a wide area is likely to injure the liver, spleen, pancreas, bladder or blood vessels. Engorgement or dilatation during physiological activity may predispose to injury. Hence it is important to know the exact character of the blow, the size of the object inflicting the trauma, the details of the accident, the time that has elapsed since the accident, and the previous consumption of food or drink as well as the record of any previous abdominal disease. A detailed and accurate history will aid in estimating the likely extent of the injury.

Examination. The examination of the patient should be thorough and painstaking with consummate weighing of the evidence. The pulse and blood pressure should be noted. A patient with pallor should suggest hemorrhage or primary shock. One of the deceptive features of abdominal trauma is that the primary shock may be transient. Certain cases that are apparently in shock may have a definite elevation of blood pressure. This hypertension has been shown to be due to extensive retroperitoneal hemorrhage or injury particularly about the kidney or adrenal. Retroperitoneal involvement must be suspected, therefore, with hypertension in abdominal trauma. If the patient is in shock a detailed examination must be postponed until treatment for its relief has been effective. However the examination when made, should be complete for injury not only of the abdomen, but of other parts of the body, as multiple injuries are not infrequent.

Abdominal distention, meteorism, localized pain and tenderness, muscle rigidity or spasm, absence or presence of peristalsis and

the type of respiratory excursion must be carefully studied. Early abdominal distention with general abdominal, but not boardlike, rigidity and absence of severe pain, particularly if there is evidence of a concomitant back injury, are indications of injury or irritation of the celiac plexus, and that a conservative policy can be planned. Increasing abdominal distention with localized tenderness and rigidity—often boardlike—severe, *persistent*, or recurrent pain, and absence of peristalsis, are indications of a visceral injury, and for immediate operation. Rectal or vaginal examination, particularly when the lesion is in the lower abdomen, may prove of great value. By this procedure, a retroperitoneal rupture of an air-containing viscus may be recognized when palpable emphysema of the pelvis is present.

Either continuous or intermittent pain that is *persistent* and *repeated* vomiting or hematemesis, rising pulse rate, and spreading local tenderness are particularly significant. Vomiting, in itself, is not pathognomonic, but repeated vomiting, or repeated hematemesis and persistent pain may be evidence of visceral injury.

One should not be deceived by a post-traumatic period of comparative comfort or relative normalcy. Years ago (1858), Pollard noted in certain instances of grave abdominal trauma, "the absence of all symptoms *indicating a mortal injury* for upward of two hours." Butler observes that with shock or alcoholism this interval may be lengthened to 6 or 8 hours. Berry has ascribed the *lack* of early significant symptoms in intestinal rupture to the fact that the immediate effect of severe injury to the intestine is a contraction of the bowel in the neighborhood of the lesion which tends for a time to prevent further extravasation of intestinal contents. This contraction may last for many hours. Cases of laceration of the intestine, stomach, bladder, and spleen have been recorded in which the patient has walked and shown no evidence of major casualty only to collapse later.

Blood count and laboratory tests. Immediate, complete blood count and urine examination should be made. Bloody urine indicates kidney, bladder, or urethral injury. If hemor-

rhage is suspected, estimation of the blood specific gravity by the falling-drop method of Barbour and Hamilton can be rapidly made, the concentration of blood plasma protein quickly determined, and prompt information obtained concerning the extent of blood loss. The estimation of blood concentration, if desired, can be checked by hematocrit determination, indications for type and amount of intravenous therapy may thus be obtained.

Radiography. A procedure that is of distinct value in the diagnosis of *intestinal* laceration or rupture is a radiograph of the abdomen. White has suggested that this be taken in the sitting posture so that free gas in the peritoneum can be better recognized by its concentration beneath the diaphragm—a crescent or sickle-shaped gas accumulation over the liver and below the diaphragm. If the patient cannot sit, White advises a lateral x-ray at the level of the diaphragm with the patient prone. Gas beneath the diaphragm when present is positive evidence of intestinal rupture, but *if absent or unrecognized it does not rule out the possibility of intestinal laceration*. Also, gas demonstrable in the retroperitoneal tissues may accompany duodenal rupture.

Intravenous urography and, in carefully selected cases, retrograde cystography and pyelography will be a great aid in the accurate diagnosis of urinary tract lesions, particularly lacerations of bladder and kidney.

Burke and Madigan have suggested the use of thorotrast as an aid in the diagnosis of lacerations of the liver and the spleen. Thorotrast is administered intravenously and an abdominal film is taken 4 hours later.

Peritoneoscopy. Peritoneoscopy may eventually prove of value in the diagnosis of certain obscure lesions but this procedure has not yet been in use sufficiently long to speak with authority concerning its applicability or indications in cases of abdominal trauma. It would seem to be contraindicated where gastrointestinal rupture is suspected. Its field of usefulness is likely to be limited.

Summary. The evidence as elaborated by history, examination, laboratory tests, and x-ray, must be carefully weighed. Abdominal examination is the most important. Severe localized or general persistent abdominal pain,

increasing pulse rate repeated vomiting, localized tenderness and boardlike rigidity with or without evidence of increasing hemorrhage or infection form a combination that demands operative interference.

All cases, no matter how trivial in which a decision for operation cannot be immediately made should be kept under the closest observation and opiates withheld. Repeated examinations should be made at least every 30 minutes until a definite conclusion concerning operation can be reached. In an obscure quiescent case illuminating symptoms such as pain distention or rigidity may have a sudden onset. Blood pressure and pulse records should be taken every 15 or 30 minutes. Blood counts should be repeated at short intervals. The repeated blood count may show evidence of hemorrhage by decreasing hemoglobin and red blood count and of advancing infection by an increasing leucocytosis. Decision for or against operation should be made within 4 to 6 hours after the accident. Any delay beyond this period may jeopardize the possibility of saving a life.

As just has stated. In spite of the most painstaking study there will always remain a number of cases in which a definite diagnosis is impossible, but the syndrome is of a type which justifies operation. In these cases an exploratory laparotomy should be done.

SHOCK

Primary shock may be due to (1) extremely painful trauma (2) severe crushing injury and (3) hemorrhage (Butler). Shock is not a necessary accompaniment of every injury moreover it shows wide variations that may not be at all correlated with the severity of the trauma. Shock should be combatted promptly by application of heat, lowering of the head, elevating of the feet, intravenous infusions of blood plasma, administration of oxygen, and injection of eschatin or adrenal cortical extract, neosynephrin, veritol, or ephedrine. If blood plasma is not available intravenous administration of gum acacia, saline and glucose or whole blood transfusions should be used. Morphia should be withheld until a decision concerning operation has been reached. Im-

mediate operation should not be undertaken until an effort to relieve shock and improve the patient's condition has been made, and a systolic blood pressure of 100 or over is obtained. However patients in shock requiring immediate operation should be treated and observed in accident wards or in or close to operating suites so that as little delay as possible occurs in inaugurating operative procedure as soon as the patient's condition justifies it.

Jaki distinguishes three stages of progression in severe abdominal trauma (1) shock (2) transient subjective improvement (3) collapse in the case of hemorrhage, or peritonitis in the case of perforation (injury) of a hollow organ.

TREATMENT

Successful treatment to obtain eventual recovery depends upon (1) prompt recognition that intra-abdominal trauma is present (2) prompt decision that an operation is necessary (3) the correct time for and method of operative interference (4) the magnitude of the injury. With multiple extensive injuries early or immediate fatality may be inevitable—the extent of the trauma placing the injured beyond the aid of any treatment.

Treatment may be either conservative or operative.

Conservative treatment is largely symptomatic but may require maintenance of fluid balance and adequate blood concentration by appropriate intravenous therapy and transfusions, especially when vomiting or hemorrhage recurs and particularly in preparation for surgical intervention early or late. In rupture of the hollow viscera, either actual or suspected particularly of the intestine or bladder some form of sulfonamide therapy is definitely indicated—sodium sulfathiazole intravenously or sulfanilamide by hypodermoclysis is preferable, as it is not likely that these drugs will be readily tolerated by oral administration. Lesions of the hollow viscera will demand early operation but solid visceral injuries, unless accompanied by persistent and unrestricted hemorrhage may more properly be considered candidates for temporary conservative measures and for delayed or late operation.

Operation may be indicated either early or late. Early operation should take place within 6 hours of the accident, particularly when injury to hollow viscera seems likely. Late operation will be demanded by evidence of progressive or recurrent hemorrhage, extensive visceral damage or local tumor formation indicating unresolved hematomas, local abscesses, or actual neoplasm (pancreatic cyst, etc.)

The common intra-abdominal lesions are lacerations or rupture of the liver, spleen, kidney, intestine, and bladder. Their specific treatment will be briefly outlined.

Liver When the patient is not moribund and when there is definite evidence of unchecked hemorrhage, operation is indicated. Without evidence of severe and persistent hemorrhage conservative treatment should suffice though with late recurrent hemorrhage operation may be required. Transfusion or blood plasma may be necessary before, during, and after operation. On exploration, if there is still bleeding from the liver this may be arrested by digital compression of the hepatic artery and portal vein at the foramen of Winslow and the laceration may be sutured or the hemorrhage controlled by tamponade and suture. Drainage should be instituted to facilitate the extra-abdominal escape of bile leaking from the laceration. If, on exploration, the hemorrhage seems controlled or has ceased it has been suggested that blood in the peritoneal cavity may be gently evacuated by suction, but clots in the rent in the liver had best not be disturbed as fatal and uncontrollable hemorrhage has occurred from overzealous efforts to suture a laceration when hemorrhage has ceased. Suture in this case is not necessary as spontaneous healing can take place. Trimble has pointed out the danger of reinfusion or transfusion of the blood taken from the peritoneal cavity in rupture of the liver. Toxic symptoms may follow, several fatal results have been recorded. Mortality rate from liver rupture is approximately 50 per cent due largely to the inefficacy of any treatment in extensive laceration.

Spleen If the patient's blood pressure is low or he is in shock—blood plasma or a transfusion should be administered. Opera-

tion should take place as soon as the blood pressure is over 100, and transfusion should be continued during and following the operative procedure. The intraperitoneal blood may be ladled or aspirated out into a sterile flask, citrated and reinfused into a vein. This may often prove a life-saving measure. Spinal anesthesia has much to recommend it. Splenectomy is to be preferred to suture or tamponade of the laceration. The mortality rate is 30 per cent largely because of associated extensive trauma.

Kidney Most of the injuries to the kidney are contusions, which heal spontaneously, and expectant treatment will suffice. However, in the remainder in which the capsule or the pelvis is torn, operation will be necessary and, if deferred too long, may not save the patient. Reported statistics indicate that 20 to 30 per cent will require surgery (Just, Lewis and Trimble, Prather, Peacock). The indications for operation are gross infection, persistent hematuria, evidence of urinary extravasation, and loss of renal function. Intravenous urography will help determine the extent of damage to the kidney and in doubtful cases may confirm the necessity for operation. Retrograde pyelography should be resorted to with extreme caution and only when indications for operation cannot be determined by other means. Peacock observed a fatal secondary hemorrhage following this procedure.

Suture of the kidney will usually suffice, but nephrectomy will at times be necessary. The recorded mortality varies from 16 to 30 per cent depending upon the frequency of multiple associated lesions and upon delay in operation in those cases requiring surgery.

Intestine Early operation after treatment of any initial shock is imperative in intestinal rupture and preferably should take place within 6 hours of the accident. Mortality mounts rapidly with delay beyond that period. Therefore, close and frequent observation and re-examination of doubtful or suspicious cases during *this interval particularly* are obligatory.

Spinal anesthesia facilitates the operative procedure which should be carried out as gently and as rapidly as possible. Suture of the laceration is usually sufficient, this is best done transversely rather than longi-

tudinally (to the long axis of the bowel) With multiple lacerations or extensive mesenteric laceration resection may be necessary. In desperate cases and particularly in large intestinal rupture, obstructive resection, exteriorization, or colostomy may be advisable. Sulfanilamide or sulfathiazole may be used locally in the peritoneum and routinely parenterally as part of the postoperative therapy.

The reported mortality is extraordinarily high. Most recent statistics cite a 60 to 10 per cent rate (Petry, Beitler, Lewis, Estes, Just). Of 1476 cases recently collected by Poer from the literature, the total mortality was 72.1 per cent and the postoperative mortality in 1914 was 59.5 per cent. This may be ascribed to peritonitis, delayed operation, large and multiple lacerations, extensive hemorrhage and to associated injuries particularly laceration of the mesentery. Early diagnosis and early operation should tend to lower what would seem to be an unnecessarily high mortality.

Bladder. In rupture of the bladder suture of the rent in its wall control of hemorrhage and drainage of the area of extravasated urine will be necessary. The rupture may be intra-peritoneal or extraperitoneal and diagnosis will be facilitated by either intravenous urography or retrograde cystography. Fracture of the pelvis is frequently a concomitant lesion. Care of the bladder tear will not interfere with its appropriate treatment. Postoperative sulfanilamide or sulfathiazole therapy will be advisable. The reported mortality ranges from 14.4 per cent (Peacock) to 6.25 per cent (Culver and Baker). It results from other associated severe injuries, massive hemorrhage from laceration of large pelvic blood vessels and delay in operation (peritonitis). Early recognition of rupture and early operation are imperative.

CONCLUSION

Nonpenetrating trauma to the abdomen may result in an injury that may be treated either by conservative means or operative interference.

Successful treatment depends upon (1) prompt recognition that an intra-abdominal

lesion is present (2) prompt decision that an operation is necessary (3) the correct time for and method of operation (4) the magnitude of the injury.

Clinically the cases may be classified into three groups: (1) Severe multiple injuries which are rapidly fatal and for which no treatment is of avail (2) cases that obviously require immediate operation (3) cases in which the diagnosis is doubtful and the indications for or against operation are not clear.

The history, careful physical examination, repeated blood counts, blood specific gravity and blood protein determinations, urine examination, and roentgenography of the abdomen should be helpful in establishing the diagnosis. In doubtful cases only by frequent repeated re-examination (30 minute intervals) will the developing evidence of a serious lesion be recognized in time to suggest operation before it is too late. Every case of abdominal trauma, therefore, no matter how apparently slight, should be kept under close observation until a sufficient interval has elapsed to determine whether an operation is indicated or not, or until recovery is assured. Lesions of the hollow viscera will demand early operation. Solid visceral injuries, unless accompanied by persistent and unrestricted hemorrhage may more properly be considered candidates for delayed or late operation. Only by close constant supervision and the prompt recognition of an intra-abdominal catastrophe demanding operation can the extraordinarily high mortality in abdominal injury be lowered.

GUNSHOT WOUNDS OF THE ABDOMEN

AMBROSE H. STORCK, M.D., F.A.C.S., New Orleans, Louisiana

THE general category of gunshot wounds of the abdomen now includes not only injuries due to bullets fired from rifles, revolvers, or machine guns, but those wounds peculiar to warfare which are caused by fragments of shells, bombs, and hand grenades, as well as the "blast" injuries produced by detonation of high explosives.

The problems involved in the management of abdominal war wounds, as well as the seriousness of such injuries, are summarized in the report of the Medical Department of the United States Army in the World War as follows: "The man with an abdominal wound presents one of the serious problems which the military surgeon has to face. No other group of cases furnishes anything comparable to it in testing the medical resources of an army, or the technical skill of its surgeons."

This review will be limited to a consideration of the modifications of procedure and the recent advances in surgical practice which, in some measure, offset the grave consequences of abdominal wounds due to gunfire.

Collection, transportation, and facilities for early treatment. Improved highways, motor ambulance transportation, and even transfer of casualty cases by airplane, have greatly facilitated the rapid removal of patients to hospitals. The importance of providing an adequate supply of oxygen and of preventing extravasation of intestinal contents due to reduced atmospheric pressure at high altitudes has been discussed by Lovelace, who advocates the use of heated sealed pressure cabin airplanes, equipped with apparatus for the administration of oxygen.

The development of mobile military surgical units has made operative treatment possible within 6, or at most 12, hours after injury has been incurred, thus reducing the number

of hopelessly delayed cases. In civil practice, the same improvements in transportation and the greater number of well equipped hospitals in small communities likewise permit more adequate and prompt treatment.

Methods for reducing the incidence and seriousness of wounds due to gunfire. The value of body armor as a means of deflecting bullets or of arresting projectiles which are travelling at such a low velocity that they would ordinarily be retained is manifest. The arguments which have been advanced for and against this method of protection, as well as a detailed discussion of various materials and designs for armor, are included in a previous report by Storck. The demonstration by Zuckerman that body ensheathment is protective against "blast" injuries coupled with the fact that body armor has been successfully used in the present European war establish the value of this preventive measure.

The possibility of reducing the severity of peritonitis caused by penetrating wounds of the abdomen through alteration of the intestinal flora by replacement with nonpathogenic bacteria, or by sterilization of the bowel contents through administration of intestinal antiseptics, has been considered in a previous communication by the present author (12). The efficacy of tetanus toxoid immunization has been proved and this simple expedient may be depended upon to avert the deaths which occur among patients with abdominal gunshot wounds who would have survived the visceral lesions alone.

Improved methods of study and estimation of the status of patients with known or suspected abdominal injuries. The duration and degree of shock and hemorrhage often determine the outcome in patients with gunshot wounds of the abdomen, and these factors are of paramount importance both in the selection of cases requiring operative intervention and in the timing of operation. Earlier detection of the existence and progress of shock and hemorrhage is now possible by combining the meth-

ods presently available for revealing changes in blood concentration with the older methods for the study of these conditions. Determination of blood specific gravity by means of the falling drop apparatus and estimation of mean corpuscular volume are simple and quick procedures which permit prompt recognition of the presence of or fluctuations in the degree of shock and hemorrhage.

Peritoneoscopy although inadequate for determining definitely whether or not visceral perforation has occurred may avert unnecessary laparotomy or on the other hand may indicate a need for abdominal exploration not revealed by other methods of examination. If proper technical precautions are observed the finding of hemoperitoneum is evidence of penetration of the abdominal wall.

Intravenous pyeloureterography and retrograde cystography make possible more accurate visualization of presence or extent of injuries to kidneys, ureters and bladder.

Treatment of shock and hemorrhage. The evolution of methods for preserving and administering whole blood and liquid or dried plasma along with the development of more accurate means of determining the degree and progress of shock and hemorrhage have in no type of surgical cases been of greater benefit than to patients with gunshot wounds of the abdomen. There are prospects that the supplies of blood elements available for use in emergencies will be further augmented through the isolation of bovine serum albumen suitable for treatment of shock and hemorrhage in the human.

Observations reported by Kekwick, Marriott, Maycock, and Whitby indicate that plasma and whole blood are equally effective for restoring blood volume, and that with large transfusions only 1 pint in each 3 pints of plasma and blood administered need be whole blood. As a rule in secondary shock, a rise of from 10 to 20 millimeters of mercury can be anticipated from every 540 cubic centimeters of blood transfused, provided that bleeding has ceased and that no other causes of loss of circulatory fluid are operating. Differentiation is to be made between primary shock due to psychogenic and neurogenic influences from which recovery rapidly occurs following rest

and the administration of morphine and secondary shock, which is indicated by a persistence of systolic blood pressure below 100 millimeters of mercury even after 1 hour of treatment by simple measures, and in which transfusion is necessary. Practically complete replacement of lost fluid is required, and at least half of this should be protein fluid, as otherwise the restoration of blood pressure will be only temporary. Transfusions of as much as 3,000 cubic centimeters within a few hours following injury may be required to afford the full benefit attainable by this type of therapy.

The demonstration by Schnedorf and Orr of the value of oxygen therapy in controlling shock has added to the presently available methods for treating this frequent concomitant condition of gunshot wounds of the abdomen. The evidences advanced by Scudder, Benner and others of the efficacy of adrenal cortex extract, as well as the observations of Best and Solandt concerning the beneficial effects of pituitary extract and concentrated serum in combatting shock, indicate that these forms of therapy are of definite value.

The thrombin preparation, which Smith and his co-workers have found to be so effective in arresting hemorrhage when topically applied, meets the need for the control of bleeding from liver lacerations when hemostasis by other means is difficult or impossible.

Management of ileus and peritonitis. By the very nature of the wounds and the operative manipulation necessary for their repair, gunshot injuries of the abdomen are inevitably accompanied by some degree of ileus and usually by more or less diffuse peritonitis.

Attempts to remove contaminating material from the peritoneal cavity by lavage are not only futile but actually increase the extent of infection and add to already existing shock. The impossibility of effectively draining the peritoneal cavity even by the introduction of multiple drains and the danger of intestinal obstruction due to the presence of drains are now generally recognized. The notoriously poor results obtained by performing enterostomy for the purpose of preventing or relieving ileus are in sharp contrast to the usually satisfactory control of this condition by doses of

morphine sufficient to maintain intestinal tone and by the use of the Miller-Abbott tube, in conjunction, if necessary, with the administration of oxygen for the removal of nitrogen from the intestine, as suggested by Fine, Banks, and Hermanson. The report by Fine, Hurwitz, and Mark concerning the serum content of the fluid present in the lumen of distended loops of bowel and the resulting depletion of plasma proteins in the circulating blood emphasizes the importance of plasma transfusion as a rational part of the therapy of ileus. Degeneration of the adrenal cortex as a result of both ileus and peritonitis occurs so constantly as to imply the need for the administration of adrenal cortical hormone or desoxycorticosterone acetate in the treatment of either or both of these conditions.

Evidences of the efficacy of sulfonamide drugs, both introduced directly into the peritoneal cavity and given parenterally, in preventing or reducing the severity of peritonitis are so numerous and convincing as to leave little doubt that these drugs should be used when peritoneal contamination has occurred.

Penicillin, the bacteriostatic fungus extract which has been the subject of a report by Florey and his associates, and gramicidin, an antibacterial substance obtained from sporulating bacilli and described by Dubos and Hotchkiss, are not rendered ineffective by the para-aminobenzoic acid present in inflammatory processes, and give promise of being useful in the treatment of infections which do not respond to the sulfonamide drugs.

Prevention and treatment of wound infection and wound rupture. The morbidity and mortality in gunshot wounds of the abdomen, due to wound rupture, are lessened by supplementing épluchage and closure of wounds by means of nonabsorbable suture materials, with maintenance of normal plasma protein levels and the prevention of avitaminosis. These same measures, particularly when combined with the instillation into contaminated wounds of sulfonamide drugs, zinc peroxide paste, or other oxidizing antiseptics, or with the delayed closure and adequate drainage of such wounds, greatly reduce the incidence of serious wound infections.

Methods for the prevention and treatment of complications. Through the parenteral administration of glucose and lactated Ringer's solutions, blood plasma, amino-acids, and vitamins, serious nutritional deficiencies can be prevented for at least several weeks.

Fatalities due to pulmonary complications can be maintained at a minimum by early mobilization and deep breathing exercises or tracheal aspiration for the prevention of atelectasis, and by prompt treatment of pneumonia with specific antisera and sulfonamide drugs. The high mortality in gunshot wounds of the abdomen when associated with "sucking" or "blowing" chest wounds can be lessened by immediate relief of tension pneumothorax and by the closure of thoracic wounds either by approximation of wound edges or the application of airtight dressings which prevent paradoxical respiration.

Recognition of the frequency with which subphrenic, subhepatic, cul-de-sac, iliac fossa, perirenal, and miscellaneous other residual abscesses occur, and adequate drainage following their early detection by means of x-ray or physical examination, avert the deaths due to these complications. Retained shell fragments or other foreign bodies present in such areas of suppuration should, as a rule, be removed at the time that drainage is established.

TREATMENT OF BURNS

GROVER C. PENBERTHY, M.D. F.A.C.S., and CHARLES N. WELLER, M.D. F.A.C.S.,
Detroit, Michigan

THE problems associated with the treatment of the severely burned patient continue to interest the clinician and the laboratory worker. A review of the literature (14) on burns published during the past 15 years indicates changing ideas and intelligent thinking regarding therapy. A few of the older principles of treatment have been continually emphasized, but as our knowledge of physiology and pathology in relation to the changes occurring in the human body increases, recent advances have been made which develop a more rational basis for therapy (18). The interchange of ideas and experiences, together with the emphasis of certain important points, have developed a better understanding of the problem. There can be no outline of treatment for general use as each burned patient deserves individual consideration. A résumé of our present form of management of the severe burn is presented together with a discussion of some of the many ideas advanced relative to present day treatment.

Prior to the publication of Davidson's work (10) in 1925 relative to the use of tannic acid it was the practice of the individual clinician as well as the various clinics and hospitals, to adhere to a routine founded on the experiences of either the surgeon or the clinic. The results obtained in many instances were assumed to be satisfactory. The statistical studies, however, showed that the results were far from gratifying. The morbidity was prolonged and the mortality was high, varying from 30 to 40 per cent (Table I).

Wells has stated the introduction of tannic acid by Davidson "has revolutionized and, apparently for the first time in history standardized the treatment of diffuse burns." The use of tannic acid in the treatment of thermal

injuries has maintained a well deserved place in the regimen of many surgeons. It is entirely in keeping with general progress in medical science that many changes have developed regarding therapy. However the basic concept of toxic absorption from the site of a severe burn which led to Davidson's work, although challenged by many, has not in our opinion been satisfactorily disproved. Like wise in many instances, criticism of the tannic acid method of treatment is unjustified due to the failure of the critics to recognize the basic surgical principles underlying this form of therapy.

FACTORS INFLUENCING THE PROGNOSIS

A combination of factors influences the prognosis for recovery in the case of every severely burned patient. The general care of the patient is of primary importance. Emphasis in recent years has been placed on the therapeutic measures of value in combating the effects of disturbances in general tissue metabolism. It is important to recognize shock and to treat this condition adequately before consideration is given to the local lesion. The extent of the burn bears some relation to the severity of shock but is not to be relied upon inasmuch as this reaction may accompany burns of a lesser degree. Shock should be treated by the application of heat, the administration of sedatives, and the usual supportive measures. Blood plasma is of definite benefit in the treatment of shock accompanying severe burns (17). Intravenous saline and glucose solutions are essential to prevent anhydremia in second and third degree burns. Hemoconcentration is present early in the case of severe burns, with the red blood cell count, blood nitrogen, and blood sugar elevated while the blood chlorides are reduced. It is doubtful if hyperglycemia can be explained as due to hemoconcentration, although dehydration will produce an increase in sugar by accelerating glycogenolysis. A

Presented at the 35th sessions on Fractures and Other Traumas, before the Clinical Congress of the American College of Surgeons, Boston, November 5-7, 1941.

lowered serum protein appearing after a few days indicates the need for a blood transfusion or plasma. Whole blood should also be given later in the course of treatment, if secondary anemia develops.

In the case of the severely burned patient, there is a rapid increase in the hematocrit reading during the first 6 hours. During the following 12 hours there is a gradual increase with very little change later. A study of the blood of a patient with an extensive burn showed that the hematocrit was 71 per cent at the end of the first hour (23), a fact indicating that there has been a loss of approximately half of the plasma volume. It was found that giving the adult 5,000 to 6,000 cubic centimeters of saline solution intravenously during a 24 hour period caused a marked drop in plasma proteins, frequently to the edema level. Similar observations have been reported by others (15, 17). Therefore, it is advisable to utilize glucose solution to combat dehydration, and to limit the use of saline. Intravenous blood plasma decreases the hemoconcentration more effectively, without causing a drop in the plasma proteins. Whole blood given with moderate amounts of saline will tend to prevent a marked drop in plasma proteins, but does not reduce the hematocrit as rapidly as plasma. Burns involving a third or more of the body in the adult are now given 1,000 cubic centimeters of blood plasma and 1,000 to 2,000 cubic centimeters of glucose and saline solutions intravenously in a 24 hour period. The remaining amount of required fluid is given orally.

Saline and glucose solutions temporarily raise the blood pressure and may be given to fortify the patient until blood is available. The temporary action of these agents is due to their rapid elimination by the kidneys, blood on the other hand is retained longer because of its protein content. Of the blood, the serum alone is vital to this action (9). Hospitals with blood banks have serum or plasma available for immediate use.

Underhill, Kapsinow, and Fisk maintain that following a burn, the permeability of the capillaries is in one direction only, namely, from the capillaries to the tissues. If only saline or glucose solutions are available, the

TABLE I—COMPARATIVE MORTALITY WITH TANNIC ACID AND OTHER METHODS¹

Author	Other methods		Tannic acid	
	No of patients	Mortality per cent	No of patients	Mortality per cent
Bancroft and Rogers (New York)	90	40.0	114	20.0
Beekman (New York)	320	37.8	114	14.9
Wilson (Edinburgh)	300	38.7	117	11.1

administration of adrenal cortex hormone may be of added benefit, as it is claimed to restore and maintain capillary tone. The clinical experiences of Wilson, Rowley, and Gray (26) show favorable results as regards the use of an extract of suprarenal cortex. Satisfactory responses have also been reported with the use of the synthetic analogue desoxycorticosterone acetate (27). Rhoads, Wolff, and Lee conclude from their observations that adrenal cortical extract is of value in the treatment of the fluid shift occurring in patients after severe burns and reduces the amount of plasma which is required to restore the circulation to normal.

There has been some question regarding the changes in blood potassium in the production of the toxic symptoms associated with severe burns. The work of Tenery showed that the whole blood potassium varied directly with the hematocrit changes and the plasma potassium findings were not important. The plasma potassium levels are usually increased during the first 48 hours. In the patients studied the potassium did not reach a toxic level. Toxic symptoms of burns were present without the presence of a toxic potassium level. Scudder found in a study of plasma potassium in 6 cases with severe burns an elevation similar to those he found in other forms of shock.

TABLE II.—REPORTED CAUSES OF BURNS TAKEN FROM THE HOSPITAL RECORDS 1922-1940¹

Cause	No. of cases	Percent

SURGICAL MANAGEMENT

An extensive burn lesion may be compared to a large open wound and deserves rigid aseptic surgical care. The importance of thorough cleansing combined with débridement of the involved skin areas, cannot be too strongly emphasized. This includes the removal of all foreign material and necrotic tissue, the opening of blebs and blisters, and the removal of loose skin, together with gentle but complete cleansing of the involved surfaces with saline and boric acid solutions. The use of green soap and solvents, such as ether and alcohol may be necessary. The burn resulting from acid or an alkali should always be thoroughly washed with water before the neutralizing agent is applied (11). Sodium bicarbonate solution is effective in acid burns, and acetic acid may be used as the neutralizing agent in burns from alkalis. In most instances the proper preparation of the burned area may be successfully carried out with little pain by the use of sedatives, such as codeine in the case of young children and morphine in older individuals. Light anesthesia may be required if the procedure necessary to prepare the involved area causes severe pain. Sodium pentathal administered intravenously by a competent anesthetist provides a satisfactory type of anesthesia for the preparation of extensive burned surfaces. (Table II.)

Failure to adhere to the basic surgical procedures in the preparation of the burned area, either because of lack of familiarity with their importance or because of existing conditions

as met with in war zones, has led to adverse criticism of the tannic acid method used in the treatment of the diffuse burns seen in civil life. In peacetime casualties are usually hospitalized within a short time, but under war conditions many days may elapse before the patient is given proper care (12). This in our opinion has been the chief factor accounting for the disappointing results of the tannic acid treatment of burns in modern warfare.

TOXEMIA OF BURNS

The factors involved in the development of the toxemia which accompanies severe and extensive burns have been widely discussed. Uniformity of opinion on this question is lacking. That infection may be responsible in many cases seems probable. On the basis of bacterial invasion of the local lesion together with the presence of concurrent infections in many young patients, we instituted chemotherapy in 1939 (18). In our first patients sulfapyridine was given orally and when sulfathiazole became available, this drug was substituted because of claims of decreased toxicity. In the absence of any accepted contraindications, chemotherapy is instituted when the temperature reaches 103 degrees F. The dosage in the case of children is calculated on the basis of weight. A total of 13½ grams per pound of weight is given in the 24 hour period in divided doses at 4 or 5 hour intervals. In the case of adults 1 gram is given every 4 hours. The dosage is then governed by frequent blood level determinations. A level near 4 milligrams per 100 cubic centimeters is desirable. Close clinical observations for complications or unfavorable reactions are necessary, and frequent blood and urine studies are advisable. A favorable clinical response with a decline in temperature is usually apparent in a few hours. There have been no deaths or serious reactions in approximately 75 severely burned patients treated to date by the addition of chemotherapy.

LOCAL USE OF SULFONAMIDE DERIVATIVES

In recent months the suggested use of certain sulfonamide derivatives as a local treatment for cutaneous burns has been proposed. This form of therapy may aid in the preven-

tion of local infection or retard bacterial invasion. Also, since the drug is absorbed, beneficial effects in the case of septicemia may be apparent. Our experience with this form of therapy is limited to an experimental study of a small group of patients treated locally with the sodium salt of sulfathiazole in a water soluble ointment base. Several patients with burns approximating 20 per cent of the total body surface have been treated and responded favorably with the formation of a dry crust, which remained intact and allowed healing without evidence of infection. We believe, however, that this form of therapy is not without certain danger. The rate of absorption is not controlled and high blood levels may occur, particularly in patients with a diminished urinary output. The formation of acetylsulfathiazole crystals in the pelvis of the kidneys and in the ureters may likewise cause serious symptoms due to obstruction. This occurred in one case in our series. Basing an opinion on our limited experience, we believe further experimental study is indicated, together with wider clinical use before local application of the sulfonamide derivatives can be generally recommended. Pickrell has recently advocated spraying cutaneous burns with a 3 per cent solution of sulfadiazine in 8 per cent triethanolamine with satisfactory results in over one hundred cases.

TANNIC ACID

The details of the tannic acid treatment have been outlined in previously published papers (4, 13, 14, 16, 18, 22), but certain important features of this form of therapy deserve repetition. The use of the freshly prepared aqueous solution of tannic acid in 5 per cent strength as a coagulant of the protein on the surface of a burned area has stood the test of time. The application by spraying has been successful and is still popular. Prepared gellies or pastes of 5 per cent or 10 per cent tannic acid strength may be substituted when the freshly prepared solution is not available. The technique proposed by Bettman (5, 6) combines the use of a solution of 10 per cent silver nitrate and a 5 per cent tannic acid solution. The tannic acid is applied either as a spray or in jelly form, followed shortly by the

Graph 1. Mortality curve before use of tannic acid treatment, — experimental period, — tannic acid and gentian violet combined with silver nitrate (10 per cent). Total cases 1,018

application of the silver nitrate solution. The claims for this technique, as stated by Bettman, have been substantiated, and we believe that this adjunct to the original tannic acid treatment has proved of distinct value.

GENTIAN VIOLET

Gentian violet in a 1 per cent aqueous solution as advocated by Aldrich (1) is preferred in burns showing evidence of infection when first seen, or in cases of more than forty-eight hours' duration when first treated. Burns involving the perineum, the hands and feet, and deep burns encircling the extremities or in the region of joints should be treated with gentian violet solution. The coagulum produced by gentian violet is more pliable and obviates splitting of the protective coating over joint areas and permits increased freedom of the hands and feet. The dye may also be combined in the treatment, after the use of tannic acid, when there is separation and evidence of infection about the edges of the coagulum.

GENTIAN VIOLET AND SILVER NITRATE

Following the experience with silver nitrate combined with tannic acid, a similar technique was used, gentian violet being substituted for tannic acid. The results in a small series of cases were satisfactory and provided the basis for a published report (8). This combination has to some extent offset certain disadvantages of the gentian violet solution when used

alone. A firmer coagulum is produced drying is more rapid and the disagreeable staining properties are somewhat limited. In addition, the antiseptic properties of the gentian violet solution appear to be increased by the combination with silver nitrate. Aldrich (2) at present advocates the use of a triple dye preparation namely crystal violet, brilliant green, and neutral acriflavine for the purpose of a more complete antiseptic action. We have had no experience with this combination.

BURNS OF HANDS AND FACE

Allen has re-emphasized and called attention to the value of aseptic surgical preparation of burns of the hand. Following thorough cleansing of the burned area, the entire surface is covered with a nonadherent type of dressing such as petrolatum gauze. A voluminous soft dressing is then applied and bandaged to exert pressure to all parts involved thus minimizing edema and the loss of tissue fluid. The part is then splinted in the position of function. Fourteen days later the original dressing is removed and the less seriously burned areas are usually found healed. Burns of the face deserve special consideration and should not be treated by any stereotype method. Tannic acid jelly may be used effectively for certain burns of this type but in other instances it may be of advantage to apply saline compresses or Blair's jelly (7) together with the application of pressure.

LATER TREATMENT

The details of the treatment following the separation of the tannic acid or gentian violet coagulum have been previously published (18). However emphasis should again be placed on the value of early skin grafting. Early grafting of extensive granulating surfaces has saved many lives and should be resorted to as soon as the local lesion is sufficiently prepared to assure successful results. This practice has also aided in minimizing scarring and deformity in many instances. (Graph 1)

CONCLUSIONS

1. It is important that careful attention be given to the treatment of shock accompanying the diffuse burn.

2. Surgical preparation of the burned area should be performed with the most rigid aseptic technique.

3. The choice of local treatment depends on the location of the burn and the time that has elapsed before therapy is instituted.

4. The maintenance of the fluid and the electrolytic balance as well as attention to the nutrition of the patient is essential.

5. Measures must be taken to combat infection with the addition of chemotherapy.

6. Early skin grafting minimizes the loss of fluid from the burned area, prevents the development of chronic infection, and aids in limiting scarring and contractures.

SOME PROBLEMS CONCERNING ACTIVE IMMUNIZATION AGAINST TETANUS

HARRIS B SHUMACKER, Jr, M D, and AUSTIN LAMONT, M D,
Baltimore, Maryland

THE present war and the consequent mobilization of millions of soldiers throughout the world have given a great impetus to the use of toxoid in active immunization against tetanus. Formerly the medical profession in general, with the notable exception of the French, had been rather indifferent to its possibilities. Protection against tetanus, however, is not only a necessary measure in time of war. Infrequent as it is in peace, tetanus is still common enough to be a matter of grave concern, especially in view of the fact that the mortality, though reduced somewhat in recent years by a better understanding of the pathogenesis and treatment of the disease, is still alarmingly high.

Although prophylactic passive immunization with antitoxin has proved very helpful, no one will deny that it leaves much to be desired. One is interminably confronted with the question whether antitoxin should be given in a particular instance. No means of properly determining this issue is available. Anyone who has been called upon to treat tetanus which has resulted from some trivial and apparently clean laceration or abrasion will know forever that it is not only deep contused and punctured wounds incurred in the street or the barnyard that may harbor actively growing *Clostridium tetani*. Tetanus not infrequently has followed an injury so inconspicuous that no doctor has been consulted, indeed, cases are sometimes seen in which no portal of entry can be demonstrated and in which, naturally, no prophylactic antitoxin has been given. Passive immunization is imperfect also because of the transient character of the protection afforded. The fall in

titer after the first week or 10 days necessitates reimmunization after this interval in all cases of persistent infection and in all of those in which manipulation or exploration must be carried out again. Even such precautions fail in those cases of latent toxemia in which the organisms have been growing unobtrusively in apparently clean and healing wounds. The usual dose may be insufficient in case of overwhelming infection. Finally, there is the question of sensitivity, a matter of great concern both in hazard to the patient and in disability and loss of time from work. It is all the more a problem because of the fact that large groups of persons requiring treatment for injuries are notoriously apt to incur other injuries necessitating subsequent injections of antitoxin, for example, industrial workers and children. In addition, there are the matters of expense and difficulty of storage and transportation. Furthermore, the modern method of warfare with its extreme mobility and lack of any fixed line of battle renders the prompt administration of antitoxin to all wounded a matter of almost unsurmountable difficulty. Obviously a more permanent active immunity which can be brought about prior to the time of injury and by a method relatively free of reactions offers many advantages.

A great deal has been learned about tetanus toxoid and the immunity it confers since Ramon and his associates demonstrated that toxin could be completely detoxified and still retain its antigenic properties and that it could be applied to clinical use (7, 34).

Two types of toxoid are available, plain and alum-precipitated toxoid. When the antigenicity of the two has been compared by individual workers the alum-precipitated toxoid has been found to produce a better antitoxin response (9, 15, 18, 29). Nevertheless, techniques have been worked out with

Foundation.

both types of toxoid which result in an apparently satisfactory production of antitoxin in the injected patient. A single injection of toxoid ordinarily causes no demonstrable production of a significant amount of antitoxin in human subjects (34). The first dose appears to sensitize or prepare the patient so that he will respond to subsequent injections by a rapid and pronounced production of antitoxin. Within 2 weeks after a second and within a week after a subsequent injection the antitoxin titer rises to an almost certainly protective level (10). It is generally agreed that a relatively long interval is preferable between the two or three doses constituting the basic course of immunization. The recommended interval varies from 3 weeks to 3 months (2 4, 10 16 19 23 26).

In addition to the type of toxoid, the number of injections, and the interval between them, the amount and antigenicity of the toxoid are important in regard to the resultant titer. In Table I are listed the antitoxin titers of guinea-pigs at varying intervals after the injection of 10 0.1 and 0.01 cubic centimeter of a commercial alum-precipitated toxoid.¹ It is apparent that the antitoxin response varies according to the amount of toxoid given. These findings are in accord with the observations of others. Gold (11) in human beings, and Sneath (30) and Trabattoni (31) in guinea pigs obtained results suggesting that the antitoxin response is greater with larger doses of toxoid. Von Eisler and Gottdenker concluded from experiments with guinea pigs that the quantity of antigen is more important with reference to the intensity of the antitoxin response from tetanus toxoid than is the case with diphtheria toxoid. Bergey and Etris thought their experiments suggested that antigenicity of toxoid is proportional to the toxicity of the toxin from which it is made. Zoeller and Ramon believed that antigenicity can be estimated from flocculation tests of the toxoid.

The experiments recorded in Tables I, II, and III were carried out in the following manner: Guinea pigs weighing approximately one gram were injected subcutaneously with 1.0, 0.1, and 0.01 cubic centimeter of alum-precipitated tetanus toxin. Blood was withdrawn after 1, 2, and 51 months and each specimen was assayed for antitoxin in the usual manner on guinea pigs. The U. S. Government standardized test toxin and antitoxin used. Some of the animals were given varying amounts of freshly assayed tetanus toxin orally in order to ascertain the degree of protective afforded, the toxin injections always being preceded by the removal of blood for estimation of antitoxin titer.

TABLE I.—EFFECT OF VARYING AMOUNTS OF TOXOID GIVEN AS A SINGLE INJECTION ON ANTITOXIN PRODUCTION IN GUINEA PIGS*

Amount of toxoid in c.c.	Antitoxin titer by American units per serum at intervals after administration of toxoid		
	1 month	3 months	1 year
1.0	10, 0.1	0.1, 0.1	10, 0.1, 0.1
0.1	<0.1, 1, 0.1	> 0.1	0.1, 0.1, 0.1
0.01	<0.1, 1, 0.1	< 0.1, 0.1	< 0.1, 0.1, 0.1

*Each figure represents an assay on an individual animal. In the table and in Tables II and III, antitoxin is indicated as follows: less than the figure given which represents the smallest amount at which the serum was assayed, > as antitoxin is almost greater than the figure cited.

When a plus is followed by +, indicating that the titer was slightly or moderately higher than the figure cited as evidenced by the number of the test animals at the end of the period of observation.

These considerations may be of the utmost importance. It is entirely within the realm of possibility I think, to produce tetanus toxin of such great toxicity that the toxoid made from it will evoke a much greater immunity and one of much longer duration. Indeed it is by no means certain that a single injection of such a potent toxoid may not bring about an antitoxin response in human subjects. One cubic centimeter of the commercial toxoids available will evoke a titer of several units in the guinea pig. Perhaps there is no fundamental difference in the reactivity of men, the usual failure to cause a demonstrable antitoxin production with a single injection being simply a matter of too small a dose or to put it in a different way of insufficient antigenicity. A comparable dose in the average adult to that given guinea pigs would be from around 120 to 150 cubic centimeters of the available toxoids. Although workers have almost universally noted no antitoxin in the serum of human beings given one dose of toxoid there are exceptions. Bergey (2) noted from 0.001 to 0.04 unit of antitoxin per cubic centimeter in 32 persons tested 90 days after a single dose of alum-precipitated tetanus toxoid. Marvell and Parish found from 0.005 to 0.01 unit several months after a single dose of alum toxoid and McBryde found after one injection of alum toxoid that 81.5 per cent of 92

children had 0.01 unit, 14 per cent 0.1 unit and 22 per cent 0.25 unit, only 2 children having less than 0.01 unit. Whether McBryde's finding of larger amounts of antitoxin in children is linked with the proportionately larger amount of toxoid per unit of body weight which they received as compared with adults on whom most of these studies have been made, is a matter to be considered.

There is no simple method of testing immunity against tetanus in man, the only method at our disposal being the bio-assay in laboratory animals of the blood serum for antitoxin. One would like to know what titer level is necessary for adequate protection. Ramon (26) was of the opinion that 0.001 international unit represented a protective level in man because horses, which he feels are of the same order of sensitivity, survive the introduction of a splinter infected with a lethal dose of spores when their serum contains this amount of antitoxin. Sneath, Kerslake, and Scruby (29) suggested that 0.01 unit per cubic centimeter is the protective level in man since this titer in guinea pigs affords protection against a lethal spore dose. Cowles concluded from antitoxin titers in man following injection of 1,500 units of antitoxin, and in guinea pigs and mice at the time of infection with spores, that 0.1 or 0.2 unit can give a fairly certain protection. Gold (12) was of the opinion that we should aim at 0.1 unit or more in active immunization because of his antitoxin estimations in subjects given 1,500 units of antitoxin. Since it is impossible to be certain what antitoxin titer constitutes a protective level, it is also impossible to state with certainty how long immunity lasts after a basic course of immunization. Numerous authors have shown appreciable amounts of antitoxin to be present months or years after a course of immunization. Gold (10) found 0.1 unit or more in 92 per cent of subjects 3 months after two injections of alum-precipitated toxoid, 71 per cent in 6 months, 56 per cent in 1 year, 30 per cent in 2 years.

The question has indeed been raised whether antitoxin titer *per se* is in reality a true index of the degree of immunity. Numerous authors have confirmed Ramon's observation that im-

TABLE II—EFFECT OF A SINGLE NONFATAL DOSE OF TOXIN ON THE ANTITOXIN TITER OF GUINEA PIGS WHICH HAD BEEN GIVEN A SINGLE INJECTION OF TOXOID ONE MONTH PREVIOUSLY*

Amount toxoid in c.c.	Toxin given 1 month after toxoid	Antitoxin titer in American units per c.c. of serum at intervals after injection of toxoid		
		3 months	4 months	6 months

	Yes	>0.05		>0.1 >0.1

*The amounts of toxin administered varied as can be seen in Table III

munized subjects will respond to a subsequent injection with a prompt rise in antitoxin titer. Analyzing reported blood serum titrations on 300 individuals after such "repeat" injections, I find that in 1 week all had 0.01 unit or more, all save 9 had 0.1 unit or more, 204 had 0.5 unit or more. There is no doubt that this capacity of the actively immunized subject to respond quickly to a repeat dose of toxoid is a most important consideration in the efficacy of toxoid as an immunizing agent.

It is important to know whether the toxin produced in the course of the natural disease will similarly serve to cause a prompt elevation of the antitoxin titer in immunized subjects. It has been known for some time that large doses of toxin are antigenic in horses, and toxin is used in conjunction with toxoid in the hyperimmunization of horses for the production of commercial antitoxin. Table II illustrates the fact that toxin brings about a decided increase in the titer of immunized guinea pigs. Three months after 1.0 cubic centimeter of toxoid has been given to guinea pigs and 2 months after varying doses of

TABLE III.—RELATIONSHIP BETWEEN SERUM ANTITOXIN TITER AT THE TIME OF INJECTION AND THE PROTECTION AGAINST TETANUS TOXIN

Antitoxin titer in American units at time of injection	Dose of tetanus toxin to produce lethal guinea pig doses from which animals succumbed or survived

*The figures cited represent the amount of toxin in G.P.L.D. per given; the figures in parentheses indicate the amount of toxin in the animal had received.

†Significance that in addition to having the animal had received an injection of toxin from which recovered.

‡The titer was >

toxin, the animals have titers exceeding 4 units per cubic centimeter whereas 3 of 5 control animals have only 3 units. Although in 4 months the titers of the controls have fallen to 1 or 2 units, those which had received toxin have titers of from 5 to more than 15 units in 6½ months. Results in animals immunized with 0.1 and with 0.01 cubic centimeter of toxoid are similar. Such studies demonstrate that toxin in sufficient but not fatal amounts serves in the course of several months to cause a significant increase in antitoxin titer. They do not, however answer the question whether this response is rapid enough to increase a low titer to a protective level before the patient might succumb to natural infection with *Clostridium tetani*. Others have attempted to answer this point with somewhat confusing results.

Jones and Jamieson (20) found that a number of actively immunized guinea pigs survived a lethal spore dose but did not respond with an increase of serum antitoxin assays being made on the seventh day and in some instances on the second, fourth, and fourteenth days. Jaulmes and Jude similarly found no increase in titer on the third, sixth, and tenth days after immunized guinea pigs had been given a lethal dose of spores from which they all recovered without symptoms. One explanation which leaves open the question of possible titer acceleration is that the toxin is neutralized as formed and has no opportunity of exerting antigenic activity (4, 17). Wolters and Dehmel found that two guinea pigs with low titers survived the introduction of splinters infected with a lethal dose of spores and showed increased titers on the sixth and eighteenth days. Zuger, Greenwald, and Gerber concluded from experiments with guinea pigs that actively immunized animals respond to toxin with increased titers on the fourth and fifth days and to infection with spores with a delayed titer rise—a significant elevation occurring first on the 8th or 10th day. This rise seemed to occur too tardily to afford adequate protection and suggested that such a rise following natural infection in man probably cannot be relied upon to give sufficient protection. Our experiments suggest that the degree of protection against tetanus toxin depends upon the antitoxin titer at the time the toxin is administered (Table III). It appears that any increase in antitoxin which the toxin may have stimulated did not reach a sufficiently high level rapidly enough to alter the outcome, unless such a rise was almost directly proportional to the titer at the time the toxin was administered. This type of study should be extended to include inquiry into the degree of protection afforded by a given antitoxin titer induced by passive immunization as compared with the same titer resulting from active immunization. It should also be determined whether a given antitoxin titer confers the same degree of protection at a time when the titer is rising at its peak or on the decrease as well as whether it resulted from a certain dose of toxoid or from a fraction of this dose. Such studies would throw addi-

tional light upon the question whether there is some immunity conferred by toxoid other than that represented by the antitoxin in the blood. Trabattoni states that immunity may persist in guinea pigs immunized with toxoid even when the serum antitoxin is diminished or absent, which he interprets as indicative of a true tissue immunity.

The general plan of immunization consists of 2 or preferably 3 injections of toxoid given at long intervals, never less than 4 weeks, and a reinjection at the time of injury. In certain instances it may be wise to keep the titer high in advance of possible injury by administration of toxoid at intervals of 6 months or a year. For such purpose the intranasal instillation of refined toxoid (topagen) is satisfactory (13). The French army uses 3 doses of the "triple vaccine" given at 3 week intervals, the British army 2 doses of plain toxoid at 6 week intervals. The United States Army uses 3 injections of plain toxoid 3 or 4 weeks apart, a stimulating dose at the end of the first year, another during the month before departure for the zone of combat unless this takes place within 6 months of the stimulating dose, and another dose at the time of injury. The United States Navy and Marine Corps use a similar plan except that alum-precipitated toxoid is used and the basic course consists of 2 injections 4 weeks apart. The demonstration that the simultaneous injection of tetanus toxoid with diphtheria toxoid or with typhoid-paratyphoid vaccine or with both is not only feasible but actually results in a higher antitoxin titer (19, 21, 27), is an important contribution. Tetanus toxoid can be easily given during the almost universally practiced immunization against diphtheria in infants and may be given advantageously to those being immunized against typhoid fever.

Ramon (26) stated that after thousands of injections no reactions of any moment had occurred. Several anaphylactic reactions in Great Britain have been reported. Cunningham and Parish and Oakley have each reported a case of nonfatal anaphylactic shock. Whittingham stated that among 61,042 members of the Royal Air Force who were immunized, 2 had anaphylactic reactions and

12 constitutional symptoms such as malaise and fever. Seven of these had urticaria. Few reactions have been reported in this country. Jones and Moss (18) noted 2 delayed reactions consisting of local soreness and fever. Hall (15) encountered 2 urticarial reactions with the second dose of plain toxoid. Subsequently (16) he encountered one delayed urticarial reaction and 2 reactions with fever and malaise on the first injection of an alum-precipitated toxoid. On giving the second injection of this toxoid to 1,800 of these persons, 7 had fever and malaise, 4 had urticaria, and 1 had anaphylaxis. The other 500 were given another toxoid which he felt was more carefully washed, with no reactions at all. Gold (14) collected from his own experience and that of other workers 1,700 cases of patients immunized with alum-precipitated toxoid in whom there were only 2 cases of urticaria. No fatal reactions have occurred, and the reported incidence of general reactions of all sorts is surprisingly low in view of the millions of persons who have been immunized. Although there is no general agreement, investigation to date tends to link the reactions to sensitization to the Witte or Berna peptone used in the culture medium in which the organisms were grown. There is reason to have confidence in the production of purer toxin by use of other media and methods of culture from which toxoids may be prepared which will cause no reactions.

The efficacy of tetanus toxoid has been repeatedly demonstrated in laboratory animals. The present armed conflict is putting to crucial test the protection afforded in man by toxoid. Active immunization is compulsory in the French and Italian armies, and is also used in the Russian army. Though on a voluntary basis, a large part of the British army has been actively immunized. I can find a record of only a single instance of tetanus in an actively immunized person, a patient reported by Simon and Patey, who had "an essentially benign and localized form of tetanus" from which he recovered. The campaign in Flanders and the evacuation from Dunkirk gave indisputable evidence of the value of active immunization (1, 25). Ninety per cent of the British Expeditionary

Force were immunized. Each wounded man was to have been given 3 000 units of anti-toxin but because of the force of circumstances the majority of the wounded reached England without having received any anti-toxin. Among approximately 1 800 wounded men who were not immunized there were 8 cases of tetanus; there were no cases of tetanus among some 16 000 wounded who had been actively immunized.

THE CLINICAL SIGNIFICANCE OF THE SERUM AMYLASE TEST IN THE DIAGNOSIS OF ACUTE PANCREATITIS

H McCORKLE, M D , and LEON GOLDMAN, M D , San Francisco, California

IN the last few years a number of clinicians have used determinations of the level of amylase in the blood serum as an aid in the differential diagnosis of acute pancreatitis. This laboratory test has been used on the University of California Emergency Service at the San Francisco Hospital for the last $3\frac{1}{2}$ years and has proved to be of considerable assistance in making a diagnosis of acute pancreatitis. In the differential diagnosis of certain other cases of acute, but obscure, abdominal disease the test has been of value in excluding the possibility of acute pancreatitis.

It is essential that the technique for the determination of serum amylase be standardized, and its accuracy confirmed repeatedly before the results can be considered significant. The normal range of serum amylase levels must be known, and their possible variations must be realized before a correct interpretation of the test can be made. We have used Somogyi's "saccharogenic" method for the determination of amylase as well as his definition of the unit. The amylolytic activity of the serum of any given normal person is usually very nearly at the same level regardless of fasting, feeding, kind of food, time of day, exercise, etc (Fig 1). Serum amylase activity in groups of normal persons is reported by most observers as being almost always within the limits of from 80 to 180 units, though Lewison reported from 40 to 175 units as the normal range in his series, and Comfort gave 320 units as the upper limit of normal. In our investigations, variations from the range between 80 and 180 units usually did not occur in normal persons, but occasionally readings below the normal limit (that is below 80 units) were found in those apparently healthy.

From the Division of Surgery of the University of California Medical School and the University of California Surgical Service at the San Francisco Hospital.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons Boston, November 3-7 1941.

A considerable elevation in serum amylase almost always occurs at some time during an episode of acute pancreatic necrosis, acute interstitial pancreatitis (acute pancreatic edema) or acute traumatic pancreatitis. Significant elevations in the amount of amylase found in the serum rarely occur except in certain phases of acute disease of the pancreas, although in certain instances acute parotitis will cause a rise in serum amylase and occasionally diseases of the kidney are accompanied by a slight elevation resulting from impaired renal excretion. Renal disease with retention of amylase is readily recognized if determinations of both serum and urinary amylase are made in all cases in which the serum amylase is only slightly increased.

In the past $3\frac{1}{2}$ years, 743 amylase determinations have been made on patients on the University of California Service at the San Francisco Hospital. Most of them were made on blood serum in cases of suspected pancreatitis, or in conditions in which differentiation of pancreatitis from other acute abdominal disease was difficult. Other amylase determinations were made on bile, urine, peritoneal fluid, and fluid from cysts. The serum amylase was studied in 43 cases of acute pancreatitis. The lowest maximum reading in any single case of this disease was 225 units, the highest was 2,459 units, and the average maximum reading was 696 units. The average undoubtedly would have been higher had not a number of the patients entered late in the course of their disease when the amylase level was probably subsiding. In 35 of the 43 cases the diagnosis was acute interstitial pancreatitis (acute pancreatic edema), in 6 acute hemorrhagic pancreatitis (acute pancreatic necrosis) was diagnosed, and there were 2 cases of traumatic pancreatitis (Table I).

In more than 200 other cases of acute abdominal disease the serum amylase test was used as a diagnostic aid to rule out the possi-

Acute traumatic pancreatitis			
Total	41	9	5

bility of acute pancreatitis. When the amylase test is done within the first 2 or 3 days of the acute illness, a low or normal reading is of considerable value in eliminating the likelihood of acute pancreatitis.

Determinations of serum amylase were made in 42 cases of acute cholecystitis (Table II). In 14 of the 42 the additional diagnosis of acute pancreatitis was made because of high serum amylase readings and in 8 of the 14 the diagnosis was confirmed by operation or autopsy. Acute pancreatitis was diagnosed in 6 of 26 cases of chronic cholecystitis because of high serum amylase readings (Table II) and in 4 the diagnosis was confirmed at operation or autopsy. Table II shows the serum amylase values found in 12 cases of stone in the common duct. Acute pancreatitis was present in 1 of these in which the amylase level was 1,875 units.

The following case reports are examples of the 3 main types of proved acute pancreatitis that show great elevations in the serum amylase level, namely pancreatic necrosis interstitial and traumatic pancreatitis.

CASE. A housewife 38 years of age complained of severe epigastric pain radiating to the back, associated with nausea and vomiting of 8 days' duration. There had been no previous attacks and there was no history of alcoholism. She appeared to be acutely ill. The abdomen was distended, there was ecchymosis in the flanks and Cullen sign was present. A large tender mass was palpated in the epigastrium. The temperature was 101.2 degrees, the pulse rate 114 and the white blood count 12,000, with 90 per cent polymorphonuclear cells. Urinalysis showed trace of albumin and slight glycosuria. The serum amylase was 1,158 units the eighth day of the illness. The icterus index was 32. The patient's temperature ranged between 100 and 103 degrees. On several occasions she developed profound shock associated with cyanosis from which she recovered temporarily following trans-

fusions of blood. On the tenth day of the disease the epigastric mass was drained through a small midline incision, under local anesthesia. A considerable amount of hemorrhagic fluid was found together with necrosis of *l* and acute hemorrhagic necrosis of the pancreas. The patient died on the eleventh day. At a topsy acute pancreatic necrosis and *l* ty degeneration of the liver were found. The gall bladder and bile ducts were normal.

CASE. A housewife 43 years of age had pain in the epigastrium and right upper quadrant of the abdomen with vomiting of 24 hours' duration. She had had a similar attack weeks previously. There was no history of alcoholism. Tenderness, spasm and rebound tenderness were present throughout the entire abdomen but were most marked in the right upper quadrant. The temperature was 101 degrees, the pulse rate 104 and the white blood count 10,000, with 98 per cent polymorphonuclear cells. The only abnormal finding on urinalysis was faint trace of albumin. The level of the serum amylase was not determined at this time. The diagnosis was acute cholecystitis. At operation the gall bladder was found to be normal but the pancreas was indurated and edematous. The serum amylase was 262 units on the first postoperative day. The convalescence was uneventful. Subsequently the patient had numerous episodes of mild abdominal pain. A very severe attack of epigastric pain occurred about 3 years later and, after 24 hours, she entered the hospital again. She appeared acutely ill. The abdomen was tender and spastic throughout with most marked findings in the epigastrium and right upper quadrant. The temperature was 100 degrees, the pulse rate 100 and the white blood count 8,000, with 8 per cent polymorphonuclear cells. Urinalysis showed faint trace of albumin. The serum amylase was 155 units on the first day and 630 units on the third day. The attack subsided spontaneously.

CASE 3. A boy 9 years of age but by an automobile fell to the street striking his left side about 1 hour before he entered the hospital. He complained of severe pain in the left upper abdominal quadrant. There was no radiation of pain and no vomiting. Tenderness, rebound tenderness, and spasm were present in the left upper abdominal quadrant. The temperature was 99.6 degrees, pulse rate 120, and blood pressure 90/80. A blood count showed 10,000 white blood cells, with 55 per cent polymorphonuclears, 80 per cent hemoglobin, and 4,800,000 red blood cells. During 4 hours' observation, the abdominal findings increased somewhat in severity.

Fig 1 This graph indicates the results of a series of serum amylase determinations taken on a normal person at various times over a period of 4 days. The readings are very nearly the same regardless of fasting, feeding, time of day, etc. The shaded area designated as "normal zone" represents the usual range of variations of normal serum amylase levels in a group of normal persons.

The serum amylase level was 2,117 units. The diagnosis was traumatic rupture of the spleen and traumatic pancreatitis. At operation, a large amount of bloody fluid was found in the peritoneal cavity. The spleen was found to have been lacerated and was removed. The tail of the pancreas was edematous and hemorrhagic. The patient recovered.

Several types of variations that may occur in the serum amylase level during an episode of acute pancreatitis must likewise be considered. In order to understand these variations a number of patients were studied over a period of several days and serum amylase determinations were made at intervals of from 8 to 12 hours. At the same time, an attempt was made to correlate the clinical course of the acute pancreatic disease with the variations in serum amylase. In this study we noted 6 types of variation of the serum amylase level in acute pancreatitis: (1) sharp rise and fall to normal, (2) sharp rise and fall to subnormal, (3) fluctuations (following the clinical subsidence of acute pancreatitis), (4) sustained high levels, (5) secondary elevations, and (6) slight increases.

In the following discussion a case report is given to illustrate each type.

1. *Sharp rise and fall to normal.* A sharp rise in serum amylase almost always occurs within a few hours after the onset of acute pancreatic disease, and the level usually remains elevated for from 24 to 72 hours, and then declines sharply into the normal zone (Fig 2). The height of the rise of the serum amylase level during an episode of acute pancreatitis does not necessarily reflect the severity or indicate the type of the acute pan-

Fig 2 (Case 4, male, aged 38) Sharp rise and fall of the serum amylase level in a case of transient acute interstitial pancreatitis associated with acute alcoholism.

creatic disease. The declination in the curve does not always correspond exactly to the subsidence of the acute process, but often it does in the acute interstitial type of pancreatitis. Occasionally the level of serum amylolytic activity declines more gradually than usual following an attack of acute pancreatitis. As far as we know at the present time, this latter finding is of no particular significance.

CASE 4. A man 38 years of age had been drinking considerable quantities of alcohol for several days before the onset of his illness. For about 48 hours prior to his entry into the hospital he had had severe burning epigastric pain radiating to the back. He vomited once. There had been a similar attack 3 years before. His abdomen was tender throughout with maximum tenderness in the epigastrium and some spasm in the same region. His temperature was 99.6 degrees and pulse rate 68. Urinalysis showed a trace of albumin but no sugar. The white blood count was 26,200 with 89 per cent polymorphonuclear cells. Serum amylase studies were taken twice daily (Fig 2). The pain and tenderness had subsided completely by the day after entry to the hospital but slight spasm remained in the epigas-

Fig. 3. (Case 5, female, aged 60 years.) Sharp rise and fall into the subnormal zone of the serum amylase level in a case of acute cholecystitis and acute pancreatitis. A second attack of abdominal pain on the seventeenth day of hospitalization was accompanied by second elevation in the serum amylase level.

trium. On the third day the patient had no symptoms or signs of his disease and left the hospital.

2. *Sharp rise and fall to subnormal level.* The final explanation of the dip below the normal zone that sometimes occurs in acute pancreatitis has not been made, although most observers believe that the extremely low levels correspond to episodes of impairment of hepatic function. The possibility that the normal zone of serum amylase activity should be reduced to include lower readings (below 80 units) must also be considered.

CASE 5. A woman 60 years of age complained of aching pain in the right upper quadrant, radiating to the tip of the right scapula, with nausea and vomiting of 12 hours duration. She gave history of

chronic cholecystitis with many episodes of colic for 40 years. She was very obese and acutely ill. The abdomen was moderately distended and guarding and tenderness were noted in the epigastrium and right upper quadrant. Her temperature ranged from 100 to 101 degrees and her pulse rate from 90 to 100. The white blood cell count was 8,600. The patient appeared to improve but because of the severe tenderness remaining in the right upper quadrant a cut cholecystitis was suspected. Cholecystostomy was done under local anesthesia. The gall bladder was inflamed and contained turbid. The amylase, the peritoneal fluid was 80.5 units and that in the bile 70 units. The amylase levels in the blood serum are shown in Figure 3. On the seventeenth day after entry the patient had a second attack of moderately severe pain and tenderness in the right upper quadrant that subsided within 48 hours. Cholangiography showed a calculus at the lower end of the common duct.

Case 9 (Fig. 7) also illustrates this fall of the serum amylase level below the normal zone following an attack of acute pancreatitis.

3. *Fluctuations within the normal zone and slightly above and below the usual normal range* (from 80 to 180 units) occur rather frequently during the days following an episode of acute pancreatitis. At present, the significance of these fluctuations is unknown. The subnormal readings mentioned are often a part of this fluctuating curve as may be seen in Figure 4.

CASE 6. A brewer 39 years of age gave history of drinking very large amounts of alcohol for a period

Fig. 4. (Case 6, male, aged 39 years.) The graph of serum amylase levels in this case of acute interstitial pancreatitis associated with acute alcoholism demonstrates the fluctuations above and below as well as within the usual normal zone, that sometimes occur following the subsidence of an attack of acute pancreatitis.

Fig 5 (Case 7, male, aged 49 years) Sustained high amylase levels in a case of acute cholecystitis and acute pancreatitis. In this case the serum amylase remained elevated for 4 or 5 days following the subsidence of signs of acute pancreatitis. Sustained high amylase levels are more often associated with a continuation, extension, or progression of acute pancreatitis.

Fig 6 (Case 8, male, aged 47 years) Moderately high secondary rise in serum amylase level that developed following the subsidence of the signs and symptoms of an attack of acute pancreatitis. In this case there were no symptoms or signs of exacerbation of acute pancreatitis to correspond to the secondary rises in serum amylase.

of 1 month. He entered the hospital complaining of severe and constant epigastric pain associated with nausea and vomiting of 18 hours' duration. The abdomen was obese and spasm and tenderness were noted in the upper part of the abdomen. The temperature was 101.6 degrees and the pulse rate 116. The white blood count was 17,300, with 80 per cent polymorphonuclear cells. The urinalysis showed a trace of albumin but no sugar. The serum amylase levels are shown in Figure 4. The pain and abdominal findings subsided in 24 hours, but fever and vomiting continued for several more days.

4. Sustained high amylase levels may be associated with a continuation, extension, or progression of acute pancreatitis, or with

acute exacerbations of pancreatitis occurring at very frequent intervals. Case 7 demonstrates sustained high amylase values.

CASE 7. A man 49 years of age complained of cramping pain which began in the left upper quadrant and radiated to the left shoulder and back. He was nauseated and vomited several times. There was a history of chronic cholecystitis and occasional episodes of severe colic in the left upper quadrant, of 10 years' duration. There was no history of alcoholism. The patient was jaundiced, the abdomen was moderately distended and there was tenderness in the entire upper part of the abdomen, most marked in the epigastrium. The temperature was 98.6 degrees and the pulse rate was 100 on entry. Blood

Fig. 7 (Case 9, female, aged 69 years) In this case in which the clinical signs and symptoms are rather typical of acute pancreatitis, the slight elevation in serum amylase is somewhat confirmatory of acute pancreatitis. This graph also shows the dip below the normal zone of serum amylolytic activity that sometimes follows an attack of acute pancreatitis.

count showed 7,600 white blood cells, with 68 per cent polymorphonuclears. The urine contained bile but was otherwise negative. On the morning of the seventh day after entry the patient had severe pain in the left upper quadrant with nausea, vomiting, and epigastric tenderness. The white blood count was 8,100 and urinalysis showed a heavy trace of albumin. The serum amylase readings are shown in Figure 5. The diagnosis was acute pancreatitis and acute and chronic cholecystitis with icterus. The acute abdominal symptoms and signs subsided over the next 3 days, but the amylase level remained elevated for more than a week and gradually declined into the normal zone (Fig. 5). Operation was performed during quiescent period. The gall bladder was still somewhat inflamed and edematous and contained many calculi, the common duct was enlarged and contained a large soft stone and the pancreas was enlarged and indurated.

5 *Acute exacerbations of pancreatitis* are often reflected in the graphic curves of serum amylase readings as secondary elevations when the patient has had more than one episode of acute pancreatitis while under observation. Case 5 (Fig. 3) serves as an example of a case of acute pancreatitis in which there was an exacerbation of the disease while the patient was in the hospital. Occasionally these secondary rises in the level of serum amylase follow a few days after an attack of acute pancreatitis without subjective or other objective findings indicative of an exacerbation of the disease. After the subsidence of an episode of acute pancreatitis, a rise in the serum amylase, not necessarily accompanied by abdominal pain may be caused by the manipulation of the pancreas that sometimes occurs during the course of surgical procedures on the bile duct.

CASE 8. A man 47 years of age complained of severe epigastric pain and vomiting of 4 days duration. He had had no abdominal pain or indigestion previously. He had used alcohol many years before but more recently. The abdomen was moderately distended and generalized tenderness and spasm were most marked around the umbilicus. The temperature was 100 degrees and the pulse rate 80. The white blood count was 5,400, with 87 per cent polymorphonuclear cells. The urinalysis was negative. The abdominal pain and tenderness subsided over a period of 3 days and the patient remained free from symptoms thereafter during his hospitalization. The serum amylase level, however, rose to 530 units on the ninth day though there were no symptoms or signs of disease at that time (Fig. 6). Operation was performed during a quiescent period. Mild chronic cholecystitis and edema and induration of the entire pancreas were found. Cholecystectomy was done.

6 *Slight increases in the serum amylase* are of relatively less diagnostic value than are the moderate or large increases that usually accompany the early course of acute pancreatitis. Slight elevations in serum amylase however may be considered as somewhat more significant when they are found in patients who present themselves late in the course of acute pancreatic disease or just after the subsidence of a typical episode of acute abdominal pain. Case 9 is illustrative.

CASE 9. A woman 69 years of age complained of severe epigastric pain and vomiting of 24 hours duration. She had had no abdominal discomfort previously and there was no history of alcoholism. Marked tenderness was present in the epigastrium. The temperature was 100 degrees and the pulse rate 70. The blood count showed 7,700 white blood cells, with 90 per cent polymorphonuclears. The urine showed a trace of albumin. The pain and tenderness subsided completely over the ensuing 4 hours. The gall bladder visualized normally by cholecystography. Figure 7 shows the serum amylase determinations.

If the clinical picture is less typical of acute pancreatitis, these slightly increased serum amylase readings must be considered equivocal. This is seen in Case 10.

CASE 10. A woman 63 years of age complained of severe pain in the right upper quadrant, with nausea and vomiting of 4 days duration. She was not particularly ill. Her previous history suggested chronic cholecystitis of many years duration. She used alcohol occasionally. There was tenderness throughout the entire abdomen, most marked in the upper right quadrant where spasm was also present. The temperature was 99 degrees and the pulse rate 70.

Fig 8 (Case 10, female, aged 63 years) The slight elevations in the serum amylase level are of relatively less confirmatory value in this case in which the clinical findings are not typical of acute pancreatitis

Blood count showed 9,300 white cells with 86 per cent polymorphonuclears. The urine showed a trace of albumin but no sugar. The symptoms and signs of illness subsided over a period of 3 days. The gall bladder was visualized normally by cholecystography. The serum amylase readings are shown in Figure 8.

SUMMARY

The laboratory determination of the serum amylase is a valuable diagnostic test in acute disease of the pancreas. Moderate to marked elevations in serum amylase activity occurring early in the course of an acutely painful abdominal condition offer confirmatory evidence of acute pancreatitis. The serum amylase test is also of some value in the recognition of acute pancreatitis occurring as a complication of cholecystitis or disease of the bile ducts.

The limitations and possible variations of the test for serum amylase must be known

before its diagnostic value can be realized. Within these limitations the test may often be of considerable assistance to the surgeon. Six variations that may occur in the serum amylase during, and immediately after, an episode of acute pancreatitis are described.

THE EFFECT OF DISTENTION OF THE SMALL INTESTINE ANOXEMIA AND OXYGEN THERAPY UPON THE FLOW OF BILE AND URINE IN THE DOG

Relationship to the Hepatorenal Syndrome

J G SCHNEDORF M.D. and THOMAS G ORR, M.D. F.A.C.S. Kansas City, Kansas

THERE has been much speculation as to the cause of the combined failure of liver and kidney function and degeneration in some cases of intestinal obstruction, peritonitis, hyperthyroidism and burns. We have tried, therefore to investigate the possible existence of a physiological basis for the occurrence of the hepatorenal syndrome in these conditions.

We first studied the effect of distention of the entire small intestine upon the flow of bile and urine. These experiments were performed upon 10 dogs fasted for 18 hours and anesthetized with sodium pentobarbital (30 milligrams per kilogram of body weight intravenously). The blood pressure was recorded from the cannulated left carotid artery. The respiration was recorded from a bellows around the chest of the dog. Bile flow was studied in 7 dogs by cannulating the common bile duct close to the duodenum after ligation of the cystic duct near the common duct. The drops of bile were recorded by an electrical recorder. A ligature was placed around the duodenum and a large cannula was tied into the terminal ileum which was also ligated distal to the cannula. The cannula was attached to a mercury manometer and an inflation bulb by means of a Y tube. The abdominal wall was closed with heavy silk suture. A control basal flow of bile was then obtained after an interval of about 30 minutes.

Intestinal distention was maintained at pressures of 20, 40 and 70 millimeters of mercury for a period of 30 minutes each. Oxygen was administered by means of a nasal

catheter to determine what effect it had upon the bile flow with the intestine distended to pressures amounting to 40 and 70 millimeters of mercury.

The excretion of urine was studied in a similar manner upon 3 dogs. Each ureter was cannulated and the flow of urine was recorded on a revolving kymograph drum by electrical recorders. A uniform mild diuretic was maintained by the continuous intravenous drip administration of 1000 cubic centimeters of physiologic sodium chloride solution over a period of 4 hours. In all of the experiments, especial care was taken to avoid the kinking of the cannulas when the intestine was distended.

Results. Intraenteric pressures of 20 and 40 millimeters of mercury resulted in a decrease in the bile flow of 7 to 42 per cent below the control level in 6 of the 7 dogs (Table I). Dog 6 showed no change. These pressures are comparable to intraenteric pressures in human cases of intestinal obstruction reported by Wangenstein. Since higher pressures may occur in some clinical cases of intestinal obstruction we distended the intestine to a pressure of 70 millimeters of mercury and found a further decrease in the bile flow in 4 dogs. Oxygen therapy lessened this inhibition in all of the dogs treated.

Nervous reflex inhibition of the flow of urine did not occur upon distention of the small intestines to pressures of 20, 40, 60, and 90 millimeters of mercury. An increase in the urine flow from 11 to 8 per cent occurred (Table II). This was attributed to an increased blood flow through the kidneys.

The blood pressure in each instance was not significantly altered by distention of the small intestine.

From the Department of Surgery and the Hixon Laboratory of Medical Research, University of Kansas School of Medicine.
Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Boston, November 3- 24.

TABLE I —EFFECT OF ACUTE INTESTINAL DISTENTION UPON THE FLOW OF BILE IN THE NEMBUTALIZED DOG

Dog No	Intraenteric pressure in millimeters of mercury				
	20 Per cent	40 Per cent	70 Per cent	70 plus oxygen Per cent	Control after release of pressure Per cent
1	-16	+5	+5		-16

4	-16	-22	-16	-5	
5	-28	-42	-38	-23	
6	0	0	-15	0	
7	-7	-14	-42	-7	0

The depth of respiration was decreased and the rate was increased by distention. Oxygen therapy decreased the respiratory rate and lessened the depression of bile flow produced by distention of the small intestine.

The second part of this investigation was concerned with the effect of anoxemia upon bile and urine flow in 10 nembutalized dogs. The blood pressure, respiration, and the flow of bile and urine were recorded upon each dog as previously described. Mixtures of 5, 10, 15, and 20 per cent oxygen with nitrogen and 100 per cent oxygen were administered by a Heidbrink gas machine. Each mixture was breathed for 30 minutes before and during the time that a tracing was taken. Five per cent oxygen was given as long as the animal could tolerate it. This was usually found to be 5 to 10 minutes.

Results Inhalation of 15 per cent oxygen in nitrogen for 30 to 45 minutes resulted in a 16

TABLE II —EFFECT OF ACUTE INTESTINAL DISTENTION UPON THE SECRETION OF URINE IN THE NEMBUTALIZED DOG

Dog No	Intraenteric pressure in millimeters of mercury				
	20 Per cent	40 Per cent	60 Per cent	90 Per cent	Control after release of pressure Per cent
1	+11	+26	+50	+81	-12

in 3 dogs the flow was increased above the normal control level.

SUMMARY

The results of our investigations so far indicate that there is a physiological basis for the combined failure of liver and kidney function in some cases of intestinal obstruction. Liver function is first impaired by a nerve reflex inhibition due to distention of the intestine.

The anoxemia present in cases of severe intestinal distention, hyperthyroidism and

burns may produce a marked decrease in the formation of bile and urine. If mild this may be a predisposing cause making the liver and kidneys more susceptible to other injurious agents. In some instances in which the anoxemia is severe, it may be the primary factor responsible for the combined failure of liver and kidney function and in some instances may produce an acholia and anuria.

Inhalations of high concentrations of oxygen are indicated when anoxemia is suspected as a factor in cases of unpaired liver and kidney function.

PRINCIPLES OF PLASTIC SURGERY IN THE TREATMENT OF MALIGNANT TUMORS OF THE FACE

HERBERT CONWAY, M D , F A C S , New York, New York

MALIGNANT tumors of the skin occur most frequently on the exposed areas of the body, especially on the face, therefore, the appearance of the lesion or the increase in the size of a long standing cutaneous growth is recognized by the patient early in the course of the disease. However, the pathway open to him is an uncertain one, since there is conflict of professional opinion as to the ideal method of treatment for malignant lesions of the skin. Fear of facial disfigurement as a result of treatment is uppermost in the mind of the patient. Undoubtedly it is due to these factors that a high percentage of malignancies of the face are recurrent lesions when they are presented for surgical excision. In the management of the slowly growing, nonmetastasizing basal cell carcinoma of the skin, as well as in the more rapidly developing and metastasizing epidermoid carcinoma, the responsibility of the profession is great, for the vast majority of these lesions are curable if treated by an adequate method early in the course of the disease. If allowed to invade the bony structures of the face and head, they may be the cause of death. Therefore, it must be clear that the cardinal principle of any treatment which may be employed with safety is the complete destruction of the lesion. The general practitioner, in his advice to the patient with an early malignant tumor, must select one of four methods of therapy: electrodesiccation, x-ray therapy, radium therapy, or primary surgical extirpation. Reports in the literature concerning recurrent carcinoma of the skin indicate that the percentage of recurrence following electrodesiccation is sufficiently high to justify condemnation of this treatment. Although x-ray treatment is an

efficient method of dealing with basal cell carcinomas, especially since it does not entail hospitalization and leaves minimal disfigurement, it has the disadvantages that therapy must be planned upon information obtained from biopsy and the entire growth is not available for microscopic study. Also the scarring of soft tissues produced by the ray may make it difficult to recognize a recurrence. Radium therapy has many of the same advantages and disadvantages as has x-ray therapy. The deforming scar which follows radium therapy often necessitates subsequent plastic excision. Surgery alone offers the satisfaction of complete extirpation of the malignant lesion and, in addition, the specimen is available for microscopic determination of the extent of its invasion. The single objection to surgery is the problem presented in the satisfactory restoration of the contour of the face—the appearance of the patient. If the removal of a malignant tumor of the face results in serious disfigurement, the patient is confronted with new difficulties, both economic and psychic, such as the loss of his job, or the development of an inferiority complex due to self-consciousness of his deformity. It is the object of this presentation to point out that, with a knowledge of the principles of plastic surgery, malignant tumors of the face can be treated successfully by surgery when first diagnosed and that the final cosmetic result is equal to or better than that of any other method. There is the additional satisfaction of knowing that the lesion has been removed completely. Once the lesion recurs following adequate primary irradiation, radical surgical extirpation certainly is justified. In this presentation certain principles of plastic surgery will be emphasized which come into play in the treatment of malignant lesions of the face and the subsequent restoration of appearance and function. If utilized by surgeons, they serve to place a high percentage

From the Department of Surgery of the New York Hospital and Cornell University Medical College

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons Boston November 3-7 1941

of carcinomas of the face in the group which can be treated satisfactorily by surgery. If carcinoma of the face is to be dealt with by the surgeon, he should be familiar with and adhere to the following principles:

1. Generous estimate in advance, of the tissue which must be removed with the lesion.
2. Consideration of Langer's lines of elasticity of the skin in planning the incision.
3. Use of the temporary Thiersch graft.
4. Indications for the use of free grafts of skin, derma, fat, fascia, cartilage and bone.
5. Use of pedunculated flaps.
6. Indications for the use of prostheses.

STATISTICS

From September 1932 to September 1940 exactly 100 patients were treated by surgery at the New York Hospital for malignancy of the skin of the face and neck. A histological classification of these tumors of the skin of the face and neck is presented in Table I.

TABLE I.—HISTOLOGICAL CLASSIFICATION

	Cases
Basal cell carcinoma	40
Recurrent basal cell carcinoma	4
Recurrent basal cell carcinoma invading bone	
Epidermoid carcinoma	
Recurrent epidermoid carcinoma	7
Epidermoid carcinoma invading bone	
Recurrent epidermoid carcinoma invading bone	
Epidermoid carcinoma of lip	
Melanosarcoma	4
Salivary gland carcinoma	3
Fibrosarcoma adenoides cysticum	
Fibrosarcoma	
Fibrosarcoma invading bone	
Metastatic carcinoma from thyroid	
Adenocarcinoma invading skin	

Basal cell carcinoma. It should be stated here that it is not a fixed policy to treat all basal cell carcinomas of the skin by surgical excision. X-ray therapy is an efficient method of dealing with these growths and may be carried out without the expense of hospitalization. Thus no time is lost from work and the therapy is effective with minimal facial disfigurement. However it is interesting to note in a study of the 40 cases of basal cell carcinoma that primary surgical excision in tumors of the skin is as effective as x-ray and that the cosmetic results compare favorably with any other method. The follow-up on

these cases shows that out of 40 there was only 1 which recurred following primary surgical excision. Thirty nine cases are free from disease 3 1/2 years after operation. The rate of survival for 3 years without disease, therefore, is 94.7 per cent. The 5 year disease free survival rate is 90 per cent. The method of surgical treatment employed in these cases was as follows: simple excision, 20 cases; excision and thick split graft, 9 cases; excision and whole thickness graft, 11 cases. The anatomical distribution of the lesions in these 40 cases was as follows: on the nose, 11 cases; cheek, 9; neck, 5; eyelid, 5; chin, 3; ear, 3; temple, 1; forehead, 2; lip, 1.

Epidermoid carcinoma. Because of the high degree of malignancy of the epidermoid carcinomas and their tendency to metastasize surgery is advised for them as a primary method of treatment. In the period of time covered by this survey, 12 cases of epidermoid carcinoma of the skin of the face and neck were treated by primary surgical excision. Anatomically these were distributed as follows: 3 cases of the ear, 3 of the nose, 2 of the cheek, 3 of the temple, 1 of the eyelids. The methods of surgical treatment were as follows: simple excision in 8 cases; excision and whole thickness graft in 1 case; excision and thick split graft in 2 cases; excision and skin flap in 1 case.

Metastatic cervical glands have been removed by block dissection or treated by x-ray therapy. Three of these patients were operated upon sufficiently long ago to be reported as 3 year cures. The follow-up at the present time shows that with the exception of 1 patient who died of heart disease 1 year after operation, all are free from disease at an average time of 1 1/4 years after operation.

Recurrent basal cell carcinoma. In this interesting group there are 15 cases including 1 in which the recurrent growth had invaded the frontal bone. The previous treatment received by these patients is listed as follows:

	Cases
X-ray therapy adequate dosage	4
X-ray therapy amount unknown	
Radium therapy amount unknown	3
Dissection	
Electric needle	
Surgical excision	
Criminization	
Method of therapy unknown	

TABLE II—MALIGNANCY OF THE FACE INVOLVING THE BONE

Case	Lesion	Operative treatment	Result
1	Sarcoma invading maxilla	Resection of maxilla temporal flap	Well after 3 years
2	Squamous cell carcinoma invading maxilla	Resection of maxilla temporal flap	Well after 4 years
3	Recurrent basal cell carcinoma invading frontal bone	Resection of frontal bone and upper eyelid scalp flap	Well after 8 years
4	Recurrent fibrosarcoma invading mastoid bone	Excision of tumor and external ear cauterization of bone prosthesis	Well after 2 years
5	Recurrent adamantinoma of mandible invading skin	Resection of mandible with parotid gland and sacrifice of facial nerve prosthesis	Well after 1 year
6	Recurrent epidermoid carcinoma invading orbit and temporal bone	Extirpation of orbit resection of orbital bones	Died 8 months after operation of direct extension of lesion to brain and distant metastases
7	Recurrent epidermoid carcinoma invading skull	Resection of portion of parietal and frontal bones over sagittal sinus thick split graft	Died 5 days after operation of meningitis and septicemia

The anatomical distribution of the lesions in these cases was as follows: 5 of the nose, 4 of the cheek, 3 of the eyelid, 1 of the temple, 1 of the forehead, 1 of the neck. The surgical treatment in the management of these recurrent lesions was as follows: excision, 2 cases, excision and thick split graft, 6, excision and whole thickness graft, 3, excision and sliding flap, 3, excision, sliding flap, and resection of frontal bone, 1 case. In all but 1 of these 15 recurrent tumors the primary treatment was other than surgery and in 12, or 80 per cent, the secondary radical excision gave a good clinical result. One tumor recurred 1 year after and another 6 years after radical surgical excision. A third patient could not be followed. Of the remaining 12 patients all are free from disease for periods varying from 1 to 8 years. Eight patients were operated upon sufficiently long ago to be reported as 3 year cures, 2 as 5 year cures, the percentage of 3 year cures, then, is 90, of 5 year cures, 66. These figures serve to emphasize the seriousness of recurrent basal cell carcinoma of the face. It is unfortunate that the primary treatment of these relatively benign lesions of the skin is inadequate so often. The most likely explanation of the situation is that simple methods of therapy afford cures in a high percentage of cases, the potential danger of these early lesions is not sufficiently emphasized, and there is a tendency on the part of both physicians and surgeons to be hesitant in recommending surgery in facial tumors because of the fear of disfigurement from postoperative scars.

Recurrent epidermoid carcinoma This group includes 9 cases, in 2 of which the recurrent lesion had invaded the underlying bone. The primary treatment in these cases was as follows:

	Cases
X ray therapy, adequate dosage	2
X ray therapy, amount unknown	3
Cauterization	2
Desiccation	1
Radium therapy	1

The anatomical distribution of the lesions was as follows: 3 cases of the neck, 3 of the eyelids, 1 of the forehead, 2 of the scalp. Extensive surgical resection was necessary in all of these cases and the surgical treatment comprised excision in 3 cases, excision and whole thickness graft in 2, excision and thick split graft in 1, excision and prosthesis in 1, excision, resection of skull, and thick split graft in 1, excision, resection of orbital bone, thick split graft in 1. Seven of these patients (78 per cent) survived operation and have been free from disease for a period of time varying from 1 to 7 years. One patient died 1 year after extirpation of the orbit and removal of a portion of the temporal and orbital bones. There was 1 postoperative death following excision of a portion of the skull for infected carcinoma of the scalp. The fact that this was a case in which it was necessary to carry out extensive resection of bone calls attention to the increased danger of radical excision when the growth has invaded bone.

There were 7 cases in which the lesion of the face had involved the bone. These are listed in Table II.

Fig 1. Case 1. a, Basal cell carcinoma of the nose, twice recurrent. Erichson and primary closure as done by means of sliding flap from the cheek as shown in b and d. The appearance 9 months after operation. Follow up examination 3 years and 4 months later showed no recurrence.

Fig 2. Case 2. a, Basal cell carcinoma of the nose. The lesion had recurred once following cauterization and twice following courses of ray therapy. Thick area presumed to be adequate. b, Shows the extent of the hole thickness graft needed for replacement. Graft as taken from the cervical region. c, The appearance of the nose 4 months after operation as performed. No recurrence had occurred 4 years later.

Fig 3 Case 3 a, Tumor of the skin and cartilage of the nose in a 32 year old man, the tumor proved to be metastatic from carcinoma of the thyroid b, c, d, e, Show the steps involved in primary reconstruction of the nose after through and through resection of the skin, alar cartilage, and mucous membrane b, The outline of a flap of skin from the upper portion of the nose The epithelium was excised from the region inferior to the flap as indicated by the dotted area c, The flap is swung downward to line the nose d, The distal end of the flap of skin has been turned back on itself to provide a smooth cutaneous margin for the nostril e, A whole thickness graft sutured in place over the raw area f, The postoperative result Examination 1 year after operation showed no recurrence in the nasal region though the patient is still receiving x ray therapy to the cervical and thoracic regions

The first and third cases in the above list will be referred to later in this report as Cases 5 and 4, respectively The 2 deaths listed above have been recorded previously in the discussion of recurrent epidermoid carcinoma

CASE REPORTS

Case 1 illustrates the use of sliding flaps from the neighborhood to cover the defect of soft tissue after excision of malignant tumor

Case 1 A W, New York Hospital No 208378, a 57 year old woman, presented herself for treatment of an infiltrating lesion of the right side of the nose which was noticed for the first time 10 years before admission and which had recurred following 2 surgical excisions performed in another institution 9 and 5 years ago Rectangular excision of this recurrent basal cell carcinoma was done and the defect was closed by means of a sliding flap of skin and subcutaneous tissue as shown in Figure 1 No recurrence 3½ years later

Free grafts of skin which are available for the repair of defects created by surgical ex-

cision of malignant tumors of the skin of the face include the following (1) the Ollier-Thiersch graft or razor graft (3), (2) the thick split graft (1), (3) the three-quarter thickness or intermediate graft (5), and (4) the whole thickness graft (2) The chief value of the Ollier-Thiersch graft lies in the fact that its epithelial surface affords cutaneous healing of the wound after excision of a growth and scar formation is prevented However, the appearance of the grafted area is unsatisfactory Therefore, the use of such grafts on the face as a final measure is condemned As a temporary method this thin graft allows for observation of the operation site for recurrence of the tumor and affords time for the preparation of a suitable flap of soft tissue The term "temporary Thiersch graft" has been coined to describe this graft, the material available for it is nearly inexhaustible for it is readily obtained from the thigh or torso The thick split graft and the intermediate graft are

Fig. 4. Case 4. a, Basal cell carcinoma which had recurred 3 times and had invaded the frontal bone and upper eyelid. b, Outline of radical excision. c, Diagram of defect after excision of tumor skin, frontal bone and upper eyelid. In one block had been made. d, Technique of forward

rotation of scalp flap. Parietal region of skull and upper eyelid were surfaced with thick split grafts. e, Postoperative appearance of patient 1 year after operation. No recurrence of carcinoma. Patient refused further reparative surgery.

thicker than the Thiensch the intermediate embodying 75 to 90 per cent of the thickness of the skin. Although some plastic surgeons use the intermediate graft for facial reconstruction because of its ready availability the whole thickness graft is preferred at the New York Hospital because of the superior cosmetic result achieved by its use. The whole

thickness graft, as implied by its name embodies all of the layers of the skin and is cut according to pattern of the defect. The use of this graft leaves little to be desired since it provides an accurate match to the adjacent skin of the face in color texture moisture and movability on the underlying tissues. The upper eyelid, from which a graft 3 by 1.5

Fig 5 Case 5 a, Fibrosarcoma of cheek invading the maxilla b, Diagrammatic representation of the defect after radical excision of tumor together with anterior wall of maxillary sinus and hard palate c, Tubed temporal flap sutured into the maxillary defect The medial portion of this flap had been converted into a double faced flap by burying a thick split graft under it at an earlier operation d, Appearance after division of the pedicle and resuture of its base into the temporal region No recurrence 3 years and 2 months later

centimeters in size can be cut without producing deformity, and the postauricular area, which may yield a graft of 5 by 3.5 centimeters, are ideal sources for such grafts. If a large graft is required a donor area on the abdomen is necessary but it must be selected with due consideration for the growth of hair.

Case 2 demonstrates the successful result obtained with the use of a free, whole thickness skin graft to surface the defect produced by the excision of a malignant tumor of the skin.

Case 2 V L, New York Hospital No 60215, a 50 year old woman, was presented for treatment of a basal cell carcinoma of the skin of the right side of the nose which was three times recurrent following x-ray therapy. At operation on September 29, 1937, this recurrent basal cell carcinoma was removed by excision as shown in Figure 2. All soft tissues were removed down to the bone and cartilage. A patterned whole thickness graft, which was cut from the posterior triangle of the neck, was sutured into the defect. Follow-up examination 4 years after operation showed no recurrence.

Case 3 demonstrates the method of rotation of a skin flap to provide a lining of skin in the repair of a through-and-through defect of the soft parts of the nose. The danger of relying entirely on biopsy material for a final tumor diagnosis is dramatically emphasized.

Case 3 J K, New York Hospital No 94807, a 32 year old man, was subjected in 1935 to subtotal thyroidectomy. Microscopic examination of sections cut from the specimen showed this to be a papillary adenocarcinoma of the thyroid. Intensive radiation was given to the neck and chest. Apparently the disease was under arrest when in February 1940 he noticed the development of a nodule over the alar cartilage of the nose on the right side. X-ray therapy

Case 2 demonstrates the successful result obtained with the use of a free, whole thickness skin graft to surface the defect produced by the excision of a malignant tumor of the skin.

Case 2 V L, New York Hospital No 60215, a 50 year old woman, was presented for treatment of a basal cell carcinoma of the skin of the right side of the nose which was three times recurrent following x-ray therapy. At operation on September 29, 1937, this recurrent basal cell carcinoma was removed by excision as shown in Figure 2. All soft tissues were removed down to the bone and cartilage. A patterned whole thickness graft, which was cut from the posterior triangle of the neck, was sutured into the defect. Follow up examination 4 years after operation showed no recurrence.

Case 3 demonstrates the method of rotation of a skin flap to provide a lining of skin in the repair of a through-and-through defect of the soft parts of the nose. The danger of relying entirely on biopsy material for a final tumor diagnosis is dramatically emphasized.

Case 3 J K, New York Hospital No 94807, a 32 year old man, was subjected in 1935 to subtotal thyroidectomy. Microscopic examination of sections cut from the specimen showed this to be a papillary adenocarcinoma of the thyroid. Intensive radiation was given to the neck and chest. Apparently the disease was under arrest when in February 1940 he noticed the development of a nodule over the alar cartilage of the nose on the right side. X-ray therapy

b

Fig. 6. Case 6. a, Recurrent epidermoid carcinoma of eyelid with extension to the globe. b, Deformity after enucleation. The sacrifice of both eyelids. The cavity has been surfaced by application of thick split graft. c, Ap-

peared to retard the growth of this lesion. The biopsy report was "apocrine adenoma or benign sweat gland adenoma. Because the appearance of the lesion suggested the invasive tendency of this tumor, radical excision was done. September 28, 1940. The entire thickness of the wall of the nose including skin, cartilage and mucous membrane was removed as shown in Figure 3. The technical problem in this case was to provide a method of repair which afforded skin to line the nasal cavity and also to surface the wound. This could have been done by the use of a double faced flap from the cheek had such flap been prepared earlier. The technique of rotation of a flap downward from the upper portion of the nose to form lining and of surfacing the area with a whole thickness graft taken from the retro-orbicular area is demonstrated in Figure 3. With the entire tumor to his disposal the examination of the pathologist was able to ascertain that it was metastatic carcinoma of the thyroid. The graft healed nicely with good cosmetic effect. Multiple pulmonary metastases developed subsequently. At the present time the patient is still receiving x-ray treatments to the lung fields.

Cases 4, 5 and 6 are examples of the surgical management of advanced malignancy affecting the eye and the bones of the face. Radical surgical excision in cases of this type calls for boldness and courage since excision of any of the facial bones produces deformity which in itself may constitute cause for complete disability. It is in the management of these patients that a knowledge of reparative techniques and of the applications of prosthe-

sis offers the prospect of cure with rehabilitation. Although in theory prostheses represent the final failure of plastic surgery, their use has served to rehabilitate many unfortunate individuals and to contribute greatly to their happiness.

ses offers the prospect of cure with rehabilitation. Although in theory prostheses represent the final failure of plastic surgery, their use has served to rehabilitate many unfortunate individuals and to contribute greatly to their happiness.

Case 4. D. W. New York Hospital No. 4, 403. 53-year-old man, in 1933 presented himself for treatment of basal cell carcinoma of the forehead invading the frontal bone. Over a period of 4 years this lesion had recurred 5 times following x-ray and radium therapy. Examination at the New York Hospital in 1933 disclosed the ulcerated lesion of the right forehead as shown in Figure 4. The growth had invaded the frontal bone, had destroyed the eyebrow, had produced some weakness of the superior rectus muscle. Vision in both eyes was good. There was extensive scar above the ulcerated area. Excision of the tumor in this case was done by Dr. George Heuer. The entire mass including the skin, the muscles of the upper eyelid, the frontal bone, and some of the frontal arched bone of the orbit was removed in one block. The frontal sinus was opened in the course of the resection. The dura mater appeared normal. Closure of the defect of the forehead was accomplished by the forward rotation of a flap hinged at the median sagittal line of the scalp. A thick split graft taken from the right thigh was used to cover the raw area on the parietal region of the skull produced by the forward rotation of the flap. A second smaller thick split graft was used to surface the right eyelid. The growth of hair in the right forehead region was arrested by means of x-ray treatment. The patient has now survived 8 years since

operation was performed. There is no local recurrence and he is in excellent general health. The appearance of the concave frontal area and the ptosis of the right eyelid have not bothered the patient sufficiently to convince him that it would be worth while to undergo further operation for cosmetic improvement.

Case 5 E. W., New York Hospital No. 192441, a 59 year old man, was examined at the New York Hospital for the first time in January 1938 because of a swelling of the right cheek and obstruction of the nasal passages on the right. Antiluetic and x-ray therapy had been administered without change in the size of the lesion. Examination showed a firm mass measuring 6 by 6 centimeters over the right maxilla. The mass was adherent to the skin and to the underlying maxilla. The nose was partially distorted as shown in Figure 5. Biopsy showed that the tumor was a retothelial (reticulocell) tumor of the face involving skin, subcutaneous tissue, and bone. On August 30, 1938, radical resection of the maxilla was done by Dr. William F. MacFee according to the technique described elsewhere by him. It was possible to save the bony floor of the orbit, the posterior wall of the maxillary sinus, the soft palate and the right upper lip. The hard palate was removed. Mucous membrane was sutured to skin wherever possible. The patient made an uneventful recovery. On March 16, 1940, approximately 7 months after resection of the maxilla a temporal flap was fashioned at operation and sutured down in place as shown in Figure 5. Division of the flap at its medial end was done on March 25, 1940. On April 10, 1940 the flap was re-elevated and two thick split grafts were taken from the thigh and buried face to face under the upper and medial end of the flap. This served to make the flap a double faced one in its distal portion. When the flap was elevated again at operation on May 6, 1940 the donor area over the frontal bone was found to be neatly surfaced by the thick split graft which had been placed at the previous operation. The pedicle was tubed by suture and its distal, double faced end was transplanted to the maxillary region as shown in Figure 5. In the final operative procedure the pedicle was detached and its base was replaced in its normal position in the preauricular and temporal regions. The patient has been equipped by Dr. Harold Genvert of this clinic with a nicely fitted upper dental plate which carries an obturator to fit into and fill the defect in the hard palate. Follow up examination 3 years and 2 months after excision of the tumor showed the patient to be in excellent general condition with no evidence of recurrence or metastasis.

Case 6 I. M., New York Hospital No. 237954, a 64 year old woman, had a tumor of the lower eyelid removed by her physician by cautery in 1936 and again in 1938. Examination in July, 1939, showed an adherent ulcerated tumor of the skin near the inner canthus of the right eyelid. The tumor involved nearly half of the upper and lower lids. There was congestion of the conjunctiva and the tumor could

be seen growing out onto the cornea. There was dimness of vision but not complete loss of sight. There was no cervical adenopathy. Enucleation was necessary to effect cure. The appearance of the lesion is shown in Figure 6. At operation on July 19, 1939 the eyeball together with both eyelids and all orbital structures was removed. Microscopy showed the tumor to be an epidermoid carcinoma. A thick split graft was applied to the wound after wrapping it about a mass of dental stent, previously molded to fit the cavity. The orbital bones were exposed in the floor of and on the medial aspects of the wound. It was not possible to preserve enough of the lower eyelid to help in the application of a prosthesis. The patient was fitted with a glass eye which is held in the socket by means of a latex prosthesis (6). This patient reports every 3 months for inspection of the grafted area. At these visits the prosthesis is retinted, replaced and held by means of liquid adhesive. There has been no recurrence to the present date, 2 years and 4 months after operation.

SUMMARY AND CONCLUSIONS

In this report an analysis is made of 100 cases of malignancy of the face treated by surgery over an 8 year period. There were 55 cases of basal cell carcinoma of which 15, or 27 per cent, were recurrent tumors when presented for surgical treatment. There were 21 cases of epidermoid carcinoma of which 9, or 43 per cent, were recurrent tumors. Study of these records shows that in the majority of the recurrent tumors, primary treatment had been inadequate. This analysis of data serves to emphasize the responsibility of the doctor to provide adequate curative primary treatment for malignant lesions of the face. In 7 cases of the 100 in the series, the tumor had invaded the bones of the face. The indications for the use of grafts, flaps, and prostheses are demonstrated by means of 6 detailed case reports. If utilized by surgeons, the principles of reparative surgery serve to assign a high percentage of malignant tumors of the face to treatment by radical surgical excision.

THE USE OF VERMILION BORDERED FLAPS IN SURGERY ABOUT THE MOUTH

BRADFORD CANNON M.D. Boston, Massachusetts

VERMILION bordered flaps have proved one of the most effective methods of correcting defects or deformities about the mouth. Although American authors commonly attribute the operation to Abbe the method was first described by Estlander in 1872 26 years before Abbe's paper appeared.

Estlander's paper was published in Swedish in the *Nordiskt medicinskt Arkiv* under the title "A Method of Replacing Lost Tissue in one Lip and Cheek from the Other Lip." A similar report from him appeared that same year in the *Archiv für klinische Chirurgie* (6). A later description of his method was published in French in 1877 (7). It is much the same as that of the original paper.

Estlander had observed that after wide excision of the lower lip for malignant disease closure was possible only with tension on the skin margins and a great difference in the width of the lips. He decried the tendency among surgeons, when confronted with a large

defect in the lip to search out and utilize remote tissues from the cheeks or neck, neglecting entirely the most available tissue—namely the other lip. While studying the anatomical relationships of the vessels about the mouth he realized that large flaps could be nourished by the encircling coronary artery alone. He determined and described accurately the relation of this vessel to the skin and mucosa of the lip and indicated the importance of this relation in avoiding injury to the vessel while preparing the flap and turning it on its narrow pedicle. Several case histories and complete descriptions of the operations are presented to indicate where and how the procedure is applicable. There are illustrative drawings of one of these cases showing how by use of this method the defect from excision of half of the lower lip for carcinoma was repaired by switching a flap from the upper lip. A new corner of the mouth was formed by the pedicle. In another case there was loss of one ala of the nose part of the upper lip and the adjacent cheek as a result of a noma. Estlander illustrates its correction with a large vermilion bordered flap turned up from the lower lip. One margin of the flap was cut across and adjusted to form

the ala, the remainder fitted to the lip and cheek. In this case also a corner of the mouth was formed by the pedicle.

Abbe's paper in 1898 was the first description of the operation in English, and the first

in which the pedicle crossed the mouth and was later severed. He reported a single case and only briefly outlined and illustrated the method. His contribution should be considered a modification of the original method.

and full credit is due Estlander for the introduction of his fundamental concept many years before.

The indications for the use of vermilion bordered lip flaps have been demonstrated and extended by surgeons in recent years (2, 3, 8, 9) and there have been modifications of the flap itself (4) but the primary principle which consists of carrying a large direct vermilion bordered flap on a narrow pedicle with a single nutrient artery has remained unchanged.

The simplest use of the flap is one in which there is a defect in the lower lip adjacent to the corner of the mouth, too large for primary closure. This method is similar to that used by Estlander in one of his illustrative cases (Figs. 1 and 2).

CASE. C. P. H. 40-73. A man 57 years of age had a large irregular ulcerated lesion of the right lower lip 1.5 centimeters in diameter which extended deeply into the substance of the lip and which proved to be squamous cell carcinoma, grade II. The operation was done under local anesthetic. The two mental nerves, the right infraorbital, and the few cervical branches that reached up and to the chin were blocked with per cent novocain. Nerve block is preferable to local infiltration because infiltration may jeopardize the blood supply to the flap by local trauma and tension within the tissues. A wide V-excision of the diseased area was then carried out. This involved removal of over half the lower lip from the corner of the mouth to beyond the midline on the opposite side and down to the alveolus. A large triangular flap, half the width of the defect, was then raised from the upper lip and cheek in the nasolabial fold and turned down and into its new position. The pedicle of the flap containing the coronary artery formed the new corner of the mouth. It was carefully sutured into place with

place in the upper lip with the pedicle crossing the mouth c, The completed repair

Fig 10 A patient in whom the prolabium was excised and replaced with a split vermilion bordered flap

deep vertical mattress sutures in the mouth and fine interrupted silk sutures in the skin. A right suprahyoid dissection was done 6 months later because of a palpable node but no metastases were found. There has been no recurrence after a full year.

This patient, before operation, was fearful that extensive relaxing incisions would be necessary in the cheek and that he might lose his job because of his appearance. The functional and cosmetic results, however, by this method, are very satisfactory to the patient.

A second method is used when the neoplasm involves the center of the lower lip. If the defect is so large that it cannot be closed primarily, a quadrangular flap extending to the corner of the mouth is shifted into the defect and the repair is completed in a similar manner to that of the first method (Figs 3 and 4).

CASE 2 C P H 22-1144 A man 56 years of age, had a large, round, ulcerated lesion of the

middle of the lower lip 2 centimeters in diameter which proved to be squamous cell carcinoma, grade I. At operation, also with local nerve block anesthesia, a wide V excision of the diseased area was carried out. This involved the removal of over one-half the center of the lower lip. A quadrangular flap of normal lip was shifted across the midline to the left, and the remaining defect was closed with a triangular vermilion bordered flap turned down from the upper lip. Neck dissection has not been done but the patient is under careful observation.

A third method is useful when there is a pre-existing defect from surgical excision of the lip for carcinoma or for other causes. A triangular or rectangular flap from the upper lip is turned into the defect in the lower and the adjacent tissues adjusted to it (Figs 5 and 6).

CASE 3 P M H 40-1003 A man, 76 years of age, had a squamous cell carcinoma, grade III of the lower lip with metastases to the neck. The excision of the lesion of the lip and a left radical neck dissection were done by Dr C C Franseen. At operation,

and full credit is due Eastlander for the introduction of its fundamental concept many years before.

The indications for the use of vermilion bordered lip flaps have been demonstrated and extended by surgeons in recent years (2, 3, 8, 9) and there have been modifications of the flap itself (4) but the primary principle which consists of carrying a large direct vermilion bordered flap on a narrow pedicle with a single nutrient artery has remained unchanged.

The simplest use of the flap is one in which there is a defect in the lower lip adjacent to the corner of the mouth, too large for primary closure. This method is similar to that used by Eastlander in one of his illustrative cases (Figs. 1 and 2).

CASE 1. C. P. H. 40-73. A man, 57 years of age, had a large irregular ulcerated lesion of the right lower lip, 5 centimeters in diameter which extended deeply into the substance of the lip and which proved to be squamous cell carcinoma, grade II. The operation was done under a local anesthetic. The trigeminal nerves the right infraorbital, and the few cervical branches that reached upward to the chin were blocked with 1 per cent novocain. Nerve block is preferable to local infiltration because infiltration may jeopardize the blood supply to the flap by local trauma and tension within the tissues. A wide V-excision of the diseased area was then carried out. This involved removal of over half the lower lip, from the corner of the mouth to beyond the midline on the opposite side and down to the buccula. A large triangular flap, half the width of the defect, was then raised from the upper lip and cheek, the nasolabial fold and turned downward into its new position. The pedicle of the flap containing the coronary artery formed the new corner of the mouth. It was carefully sutured in place with

HYPOPROTHROMBINEMIA AND LIVER FUNCTION

S E ZIFFREN, M D, C A OWEN, M D, E D WARNER, M D, and
F R PETERSON, M D, Iowa City, Iowa

PLASMA prothrombin and methods for measuring this clotting factor have attracted much interest in recent years. Even before the need for vitamin K was known, it had been shown (18, 22) that intact liver function is necessary for the production of prothrombin. With the widespread clinical use of vitamin K, it soon became apparent that liver disease interferes with the prothrombin response to vitamin K therapy in human patients (4, 5, 6, 13, 16, 19, 20). Additional studies with liver extirpation confirmed the vital rôle of the liver in prothrombin production (1, 20, 23). Hypoprothrombinemia, thus, may result either from a deficiency in vitamin K, or from liver disease. This necessity of a good state of liver function to maintain normal prothrombin production naturally has suggested the possible use of the prothrombin level as a measure of liver function. Wilson (24, 25) studied the correlation of the prothrombin level and the hippuric acid liver function test and concluded that these two usually gave parallel results and reflected the state of the liver much better than did other liver function tests. More recently Lord and Andrus (8) and Olwin (11) have stressed the value of the prothrombin level and the response to vitamin K in the differential diagnosis of intrahepatic and extrahepatic jaundice. On the other hand, Lucia and Aggeler (10) found little correlation between the hippuric acid liver function test and the prothrombin level. Lucia and Aggeler used the prothrombin method of Quick (14, 15) whereas the others used the two stage method of Warner, Brinkhous and Smith (18, 22). It appears probable that differences in the prothrombin methods employed are responsible for the differences in the results obtained by these workers.

We wish to present studies correlating the plasma prothrombin level with other evidence of liver disease, and, particularly, to compare the results obtained with different prothrombin methods. The data obtained so far indicate that in human patients hypoprothrombinemia which does not respond to vitamin K therapy is a reliable index of liver disease and that prothrombin techniques differ in sensitivity in this respect.

Before presenting the cases studied, we wish to give a brief résumé of the prothrombin methods available. The several prothrombin methods in current use in this country fall into two groups and can be classified as one stage and two stage methods. In the two-stage procedure, developed by Warner, Brinkhous, and Smith (18, 22), the prothrombin of plasma is converted into active thrombin as a preliminary step. In a second step, the thrombin thus produced is measured by determining the speed with which it will clot a standard fibrinogen solution. In contrast, the one stage methods simply measure the clotting time of blood or plasma in the presence of excess thromboplastin. These latter methods, thus, are dependent upon a summation of the time required for the thrombin to act in clotting. They serve as a very practical index of the capacity of the blood to clot and, thus, of the tendency of the patient to bleed. The method of Quick (14, 15) and the more simple "bedside" test (27) developed in our laboratory, which gives essentially the same results as the Quick's method, are of this type. Also several modifications (3, 7, 26) of these are in this category.

All of the methods in current use give satisfactory results for the clinical control of vitamin K therapy, and all serve to detect the hypoprothrombinemia which results from acute severe liver injury. However, with milder degrees of hypoprothrombinemia, particularly if of a chronic nature, it appears that an altered convertibility of prothrombin

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Boston, November 3-7, 1941.

8 months later a triangular vermilion bordered flap was raised from the left upper lip. There was no hazard in using this flap because although the left facial artery had been severed during the neck dissection that on the right which is the side from which the flap is nourished, was intact. By extending an incision obliquely downward from the right border of the defect of the lower lip, triangular space was created in which the flap was fitted. The second flap, thus formed from the lower lip, as shifted to the newly created corner of the mouth on the left and adjusted to the adjacent cheek.

A fourth method similar to that described by Abbe is useful in the secondary correction of unilateral harelip deformities. The tight upper lip and the often deficient floor of the nose can be improved by utilizing a flap from the lower lip giving a more pleasing relationship between the two. By this method both the fullness of the lower lip is reduced and tissue is added to the upper lip. The pedicle which must cross the mouth is severed after 2 to 3 weeks (Figs. 7 and 8).

CASE 4. M. G. H. 126720. Patient is girl, 5 years of age. The primary repair of the lip, done in childhood, left her with tense retracted upper lip, deficient floor of the nose and unfortunately slightly suture marks on both cheeks. At operation, under tracheal ether anesthesia, the difference in width between the two lips was determined and a vermilion bordered flap half this width was prepared in the midline of the lower lip. The old scar in the upper lip was opened and extended into the floor of the nose. The flap was turned to this defect the vermilion borders were accurately approximated, and the tip of the flap was fitted into the floor of the nose. Two weeks later the pedicle of the flap was severed and the mucosal edges were closed. Most of the operative procedures were carried out by D. S. H. Sturge.

A fifth method is useful for secondary corrections following harelip repair when there is nasal symmetry. The lip is opened in the midline with extensions across the base of the columella into the floor of each nostril. A split vermilion bordered flap is used. The splitting of the flap leaves a better balanced lip with scars that are not apparent (Figs. 9 and 10).

CASE 5. M. G. H. 59, 7 patient of D. M. S. Strock. A girl, 3 years of age had partial double harelip repaired in childhood. In the initial repair the proboscis was utilized to form the vermilion border in the midline. Because of the notching of the upper lip and because of the deficiency of tissue

bulk in the proboscis, a split vermilion bordered flap from the lower lip was used. At operation, under general anesthesia instead of opening the lip in the midline as indicated in the diagram, the proboscis was completely excised in this case and replaced by the flap.

When the pedicle of the flap forms a new corner of the mouth, as in the first 3 cases, it can later be severed just as is the pedicle that crosses the mouth. In this way the width of the opening is increased and the patient can use the mouth more comfortably. It is important, however, not to extend the incision laterally beyond the pedicle of the flap as the patient may then have difficulty in controlling the corner of the mouth and in preventing the leakage of saliva. After the patient has become accustomed to the altered condition of the mouth there is seldom much difficulty with function for sufficient residual muscular action remains to control the motions of the mouth. The scars of the face and lips resulting from the procedures are not disfiguring because they lie in the nasolabial fold and vertically on the lip. Little distortion of the mouth is caused by the scars either at rest or while the mouth is in motion.

SUMMARY

The vermilion bordered lip flap was first described by Eastlander in 1872. It is useful in repairing the lip after a wide excision for carcinoma, as the need of widespread relaxing incisions in the cheek is eliminated and no normal tissue is sacrificed. It is also useful for the secondary correction of harelip deformities both in securing a better balance between the upper and lower lips and in replacing deficiencies in the floor of the nose. Five cases in which the flap was used are presented.

Fig 4 Prothrombin response to vitamin K therapy Central liver necrosis - • - -, Bedside technique, —○—, two stage technique

The amount of prothrombin, as indicated by the two stage method, was greatly reduced. The clotting power of the blood, however, as indicated by the one stage method was only moderately impaired. As would be expected in cases in which the lowered prothrombin was due primarily to liver disease, vitamin K did not correct the hypoprothrombinemia. A poor and incomplete response was indicated by the one stage test, but no response was demonstrable by the two stage test. The patient came to autopsy and an extreme degree of cirrhosis of the liver (Fig 2) was found. This marked liver damage, indicated by the ineffectiveness of vitamin K, was mainly responsible for the hypoprothrombinemia.

Figure 1, C, represents a case of Banti's syndrome. Here again, the hypoprothrombinemia was associated with extensive liver damage and the administration of vitamin K was ineffective. As in the preceding case, the two stage prothrombin method proved to be a more sensitive index of the liver damage than did the one stage test. The hypoprothrombinemia, as indicated by the two stage method, was much more severe than was apparent from the one stage test. Also, the ineffectiveness of vitamin K was more evident by the two stage method. We have noted that there is usually some shortening of the one stage clotting time following vitamin K therapy, irrespective of the type case with which we

are dealing. The biological significance of this fact is not yet apparent. This patient died following splenectomy and the liver (Fig 3) showed extensive cirrhosis.

Figure 4 represents a case of hepatitis with jaundice. In this case the prothrombin level showed some response to vitamin K by both methods, indicating, we feel, that there was some deficiency of this vitamin. The main cause for the lowered prothrombin, as well as of the jaundice, however, was the liver damage, and the more sensitive two stage prothrombin method indicated a very incomplete response. This patient was explored and the

Fig 5 Microscopic section of liver in case of severe hepatitis with jaundice

Fig. 1. Prothrombin response to vitamin K therapy. A, Stricture of bile duct. B, portal cirrhosis. C, Bant's stage technique.

may compensate for a considerable decrease in the actual amount of prothrombin present (12-28). In instances of this type, the two stage method appears to be a much more sensitive index of the true prothrombin level than are the one stage methods and, therefore is a better index of liver function.

Figure 1 A, represents a case in which an obstruction of the common bile duct resulted in vitamin K deficiency. The hypoprothrombinemia, shown by both the two stage and the one stage methods responded promptly and completely to the administration of the vita-

min. In this case by all available criteria, the functional capacity of the liver was within normal limits and the lowered prothrombin was due entirely to a vitamin K deficiency.¹ This case illustrates the normal response to vitamin K therapy.

Figure 1 B represents a case of portal cirrhosis of the liver. Bile was present in the bowel, and there was no reason to suspect that the vitamin K intake was inadequate.

¹It is noted that for the purpose of summary, treatment response with the greatest speed, the best way to administer the vitamin is by the intravenous injection of one of the synthetic water soluble preparations.

Fig. 2. Microscopic section of liver from case of extrahepatic cirrhosis of liver which did not respond to vitamin K therapy.

Fig. 3. Microscopic section of liver showing extrahepatic cirrhosis, from case of Bant's disease. This did not respond to vitamin K therapy.

Fig. 6. Prothrombin level temperature — pulse, and respiration in case of thyroid crisis with recovery

extrahepatic biliary tract was found to be entirely normal. The very gradual return of the prothrombin level to normal coincided with clinical recovery of the patient. A biopsy of the liver at the time of exploration showed extensive liver necrosis (Fig. 5). This case is one in which the extensive liver damage, indicated by the two stage method, strongly suggested that the jaundice was of intrahepatic origin before exploration, and illustrates the usefulness of prothrombin studies in differential diagnosis as well as in prognosis.

During the past few years, increased emphasis has been placed on changes occurring in the liver associated with hyperthyroidism, (2, 9, 17). Figure 6 represents a case of thyroid crisis with recovery. The preoperative and postoperative prothrombin levels were moderately reduced indicating moderate impairment of liver function in this case. Still more striking is a recent fatal case of post-

operative thyroid crisis. In this patient the prothrombin level as determined by the two stage method fell to 16 per cent of normal. Vitamin K therapy was instituted, but the patient died before a second prothrombin determination could be made. Extensive hemorrhage, no doubt due to the lowered prothrombin, was at least a contributing factor in the fatal outcome. These 2 cases, of course, are not sufficient to justify ultimate conclusions, but they are in accord with the thesis that hepatic insufficiency is an important factor in fatal thyroid crisis.

In all of the cases we have studied the two stage procedure has appeared to be a more sensitive index of liver damage than have the one stage tests. If further work establishes prothrombin determinations as a useful index of liver function it may be that some simplification of the two stage test can be developed which will render it more suitable for general use.

SUMMARY

From our results, as well as from reports in the literature it appears that determination of the prothrombin level has considerable promise as an index of liver function. Hypoprothrombinemia due to a vitamin K deficiency responds rapidly to specific therapy. Failure to obtain this response appears to indicate liver disease.

Unfortunately it appears from the work to date that the simple one stage tests, which have proved so satisfactory for the control of vitamin K therapy, are not nearly as sensitive an index of liver damage as is the more complicated two stage method. The latter method could probably be simplified.

Preliminary studies of prothrombin levels in thyroid crisis lend some support to the thesis that the liver is concerned in this condition.

Fig 6. Prothrombin level, temperature, pulse, and respiration in case of thyroid crisis with recovery

extrabepatic biliary tract was found to be entirely normal. The very gradual return of the prothrombin level to normal coincided with clinical recovery of the patient. A biopsy of the liver at the time of exploration showed extensive liver necrosis (Fig 5). This case is one in which the extensive liver damage, indicated by the two stage method strongly suggested that the jaundice was of intrabepatic origin before exploration, and illustrates the usefulness of prothrombin studies in differential diagnosis as well as in prognosis.

During the past few years increased emphasis has been placed on changes occurring in the liver associated with hyperthyroidism, (2, 9, 17). Figure 6 represents a case of thyroid crisis with recovery. The preoperative and postoperative prothrombin levels were moderately reduced indicating moderate impairment of liver function in this case. Still more striking is a recent fatal case of post

operative thyroid crisis. In this patient the prothrombin level as determined by the two stage method fell to 16 per cent of normal. Vitamin K therapy was instituted, but the patient died before a second prothrombin determination could be made. Extensive hemorrhage, no doubt due to the lowered prothrombin, was at least a contributing factor in the fatal outcome. These 2 cases, of course are not sufficient to justify ultimate conclusions, but they are in accord with the thesis that hepatic insufficiency is an important factor in fatal thyroid crisis.

In all of the cases we have studied the two stage procedure has appeared to be a more sensitive index of liver damage than have the one stage tests. If further work establishes prothrombin determinations as a useful index of liver function it may be that some simplification of the two stage test can be developed which will render it more suitable for general use.

SUMMARY

From our results as well as from reports in the literature it appears that determination of the prothrombin level has considerable promise as an index of liver function. Hypoprothrombinemia due to a vitamin K deficiency responds rapidly to specific therapy. Failure to obtain this response appears to indicate liver disease.

Unfortunately it appears from the work to date that the simple one stage tests which have proved so satisfactory for the control of vitamin K therapy are not nearly as sensitive an index of liver damage as is the more complicated two stage method. The latter method could probably be simplified.

Preliminary studies of prothrombin levels in thyroid crisis lend some support to the thesis that the liver is concerned in this condition.

THE HEALING OF ANASTOMOTIC WOUNDS IN ASEPTIC GASTRIC SURGERY

FRANK GERBODE, M.D. *San Francisco, California*

THE object of this paper is to report some of the work done in the experimental laboratory during the development of a technique for aseptic gastric surgery. During the past 2 years all gastric operations on the surgical clinic service at the Stanford University Hospitals have been done with a closed or aseptic procedure. The technique of this operation and the clinical experiences with its use have been reported by Dr. Emile Holman. In the early stages of the conversion from open anastomosis to an aseptic technique certain questions arose relative to the use of clamps, methods of suturing and the healing of wounds made with the cautery.

Although aseptic anastomosis in the intestine has been practiced for many years the use of this principle in gastrointestinal surgery has found few advocates. Wangensteen (14) recently described a method of doing closed anastomoses adaptable to any segment of the alimentary canal and followed this publication with another (15) in which he described his experiences with the technique after using it in 100 consecutive cases. As Wangensteen indicated probably the following two factors more than any others, have deterred surgeons from using a closed anastomosis: namely, danger from hemorrhage and fear of poor mucosal healing if the mucous membranes are not approximated.

Three choices are open to the surgeon in preventing bleeding in gastric surgery. The first is the clamping and ligating of the individual gastric vessels, which method is tedious and necessarily involves spilling some blood and gastric content into the operative field. The second is the use of a continuous hemostatic suture as an inner layer which

must be placed tightly enough to constrict the vessels. Such constriction is injurious to the tissues. Healing with this type of suture has been found to be poor and is attended by considerable edema and infection (9). The third method is the use of the cautery to scar the wall sufficiently to coagulate the vessels.

Few studies have been reported on the healing of gastrointestinal wounds made with the cautery. Klose and Rosenbaum-Canné believed that section by cautery produced more inflammation and delayed union than did division with knife. Their observations were made on 16 cats in which simple incisions were made through the wall of the stomach, these wounds being closed with various methods of suturing. Kopyloff studied the comparative healing of gastroenterostomies, the incisions being made with scissors, knife and cautery and sutured by different methods. His results led him to believe that cautery incisions caused pronounced inflammation and delayed healing. His work throws little light on the subject, however, since in the 8 animals in which cautery incision was done the specimens were removed between 25 and 180 days after operation. Only 1 early specimen was studied.

The healing of gastrointestinal wounds made with the scalpel or scissors, and the effect of using various suture materials and methods have been described amply by others. Martzloff and Suckow (9) in 1933 summarized the literature on wound healing in gastroenterostomy and reported observations on 44 dogs. They found that the most rapid healing was obtained by the use of a single layer of Halsted serosubmucosal protection sutures of silk. They were of the opinion that separate suture of the mucosa was unnecessary and actually retarded healing. Furthermore sutures placed to evert the mucosa often caused epithelium to develop in the line of gastrointestinal apposition, resulting in adenomatous

Presented at the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Boston, November 2-7, 1941.

structures Their findings indicate that healing takes place more rapidly when the mucosa is left unsutured

PLAN OF STUDY

Twenty-seven full grown dogs were used They were given only water for 24 hours preceding the operation One hour before operation, morphine sulphate, 2 grains, was given hypodermically Anesthesia was maintained with inhalation ether In 17 animals an aseptic anterior gastroenterostomy was done and in 10 animals aseptic gastric resection was performed The Waffler cautery was used to divide the stomach and intestine After operation the animals were fed water the first day, milk the second, milk and gruel the third and fourth, and from then on, the standard dog chow They were sacrificed with chloroform at from 1 to 3 day intervals from the 2d to 34th day Specimens were removed while the animals were living, and were fixed in formalin Segments were cut from the midportion of the anastomosis, embedded in paraffin, and the sections were stained with hematoxylin-eosin and van Gieson

OPERATIVE PROCEDURE

The procedure used in these experiments was the same in principle as the one reported by Emile Holman In the early experiments the gastric resections were done with the use of only Payr clamps at the line of transection, the suturing then being done over these same clamps In the more recent experiments, the Payr clamp was replaced, after the wall was crushed, by either a Martzloff or a Wangenstein clamp Another crushing clamp was applied distal to the anastomosis clamp and the intervening segment of stomach wall was divided with the Waffler cautery A 3 millimeter cuff of tissue was left protruding beyond the clamp and this cuff was then seared for 15 seconds with the cautery Reasons for leaving the cuff are given below The jejunal stoma was made by excising with the cautery a segment of the antimesenteric wall protruding beyond an anastomosis clamp, again allowing the seared cuff to project 3 millimeters beyond the clamp Preliminary crushing with a Payr clamp was not found to be

necessary in the jejunum In the simple gastroenterostomies the stomach opening likewise was made by excising a segment of the anterior gastric wall protruding beyond an applied anastomosis clamp, the same 3 millimeter cuff being left projecting beyond the clamp An assistant held the anastomosis clamps while the sutures were placed

The prevention of hemorrhage in closed anastomoses presented a problem which was solved after we had experimented with various means of treating the divided end of the stomach It was found that crushing alone did not prevent bleeding Furthermore, if one simply and rapidly cuts the stomach from the anastomosis clamp with the actual cautery, brisk hemorrhage may result when the clamps are withdrawn Heating the anastomosis clamp with the Waffler cautery for 20 to 30 seconds will insure coagulation of the vessels, but this method has the disadvantage of damaging the contiguous stomach wall by heat transmitted from the clamp The one fatality in the series occurred in an animal in which this method was used, death was due to localized peritonitis resulting from sutures giving way in an area damaged by transmitted heat When the electrocoagulating unit was applied to the anastomosis clamp, it was found that high voltage for a long period of time was necessary to prevent bleeding, producing the same injury as did heating the clamp with the actual cautery

These experiences led to the adoption of the method of leaving a 3 millimeter cuff of tissue protruding above the clamp when the stomach or intestine was resected When the cuff was seared with the actual cautery at bright red heat for 15 seconds most effective hemostasis resulted, and damage to the tissues beneath the clamp was prevented A study of early specimens showed that this cauterized cuff had disappeared almost entirely in 48 hours, probably from the action of the digestive juices In no instance did it lengthen the flange or cause obstruction The area crushed with the Payr clamp formed the granulating bed The large vessels which approached the line of anastomosis were underrun with a silk suture on an intestinal needle and then tied

Fig. 6 Twenty-one day healing, Dog 9, gastroenterostomy scar: *a*, line of apposition; *b*, healed mucous membrane; *c*, lymph gland formation; *d*, intestine; *e*, stomach.

Fig. 7 Twenty-eight day healing, Dog 10, gastric resection scar at line of apposition: *a*, mucous membrane; *b*, lymph glands; *c*, site of union; *d*, intestine; *e*, stomach; *e*, area of lymphoid hyperplasia. Not absence of flange.

stages of healing except near the base of the granulating bed. By the eleventh day the line of serosal union was replaced by a zone of fibrous tissue in which the frayed ends of the muscularis could be seen.

SIZE OF THE FLANGE

Beginning with the 14 day specimens there was a definite decrease in the height of the flange. By the 18th day it was considerably smaller and in twenty-eight days the site of union was represented only by an area of slight thickening. It would appear that irritation from a granulating bed has something to do with maintaining the flange for

as soon as it was covered with mucosa the flange regressed.

MICROSCOPIC DESCRIPTION OF REPRESENTATIVE SPECIMENS

Figure 1 5 day—Dog 5—gastroenterostomy. The line of apposition showed minimal inflammatory response. A broad granulating bed, as present, covered by fibrinocellular membrane. The chronic suture was surrounded by collection of polymorphonuclear leucocytes. On the stomach side of the defect the epithelium had begun to grow out as single layer. On the intestinal side the epithelium also had begun to cover the ulcer but there was less growth than from the stomach side. The mucous

Fig. 8 Thirty-two day healing, Dog 9, gastric resection: *a*, line of apposition; *b*, healed mucous membrane; *c*, lymph glands; *d*, intestine; *e*, stomach.

Fig. 9 Six day healing, Dog 9, gastroenterostomy. High power photomicrograph showing single layer of epithelial cells growing from stomach side: *a*, granulating bed; *b*, fibrinocellular membrane; *c*, marginal cysts; *d*, early gland formation.

membrane adjacent to the defect showed some edema and cellular infiltration

Figure 2 9 days—Dog 22—gastroenterostomy The line of apposition was filled with a thin layer of fibrin in which there were only scattered leucocytes The granulating bed was about one-third the diameter of the 5 day specimen The epithelial growth on the stomach side showed early gland formation and 3 marginal cysts There was about an equal amount of epithelial regrowth and gland formation on the intestinal side

Figure 3 11 days—Dog 24—gastroenterostomy The line of apposition was practically obliterated by a fibrous tissue zone Some granular debris was present in this region On one side the epithelium had grown over the entire granulating bed, being joined in the center by a narrow area of single celled epithelium In another area the mucous membrane had not healed, the appearance being that of a 7 day specimen Well defined gland formation was present

Figure 4 14 days—Dog 2—gastric resection The line of apposition was replaced by fibrous tissue The mucous membrane lay in apposition There was definite gland formation, especially on the stomach side of the anastomosis The granulating bed was covered by a single layer of epithelium A silk suture in the muscularis was surrounded by a collection of polymorphonuclear cells The flange was smaller than the earlier specimens
